Vaso-occlusive pain in a child with sickle cell disease	1. Vital signs q 4 hr 2. Record I + O, daily weight 3. Continuous pulse ox. if any respiratory symptoms present, or if on parenteral opiates 4.Consider CR monitor	1. CBC, diff., plt count and retic count initially (compare with patient's baseline data); consider a hold tube for the blood center (for later type and cross) if severe anemia suspected or transfusion anticipated 2. CXR: low threshold if cough or any respiratory signs or symptoms are present, or develop after admission; encourage incentive spirometry prior to CXR 3. Blood culture if >38.2°C; urinalysis, urine culture and other cultures (e.g. CSF) as indicated 4. Consider diagnostic tests to evaluate possible non-sickle causes of pain (e.g. abdominal ultrasound, liver function tests for RUQ to R/O cholelithiasis and cholecystitis)	1. IV + PO 1.25 x maintenance. Increased fluids only if patient is dehydrated and/or insensible losses are increased (e.g. persistent fever); avoid excessive fluids, which may worsen respiratory status 2. Avoid IV fluid bolus unless clinically dehydrated or clinically indicated (not for pain alone) 3. Incentive spirometry–10 breaths q 2 hr. from 0800–2200 and while awake. 4. Encourage ambulation and activity	1. Follow patient-specific care plan if available; if not, follow generic steps below 2. Offer heat pads, imagery, relaxation methods or other comfort measures as adjunct to pharmaceuticals. 3. A parenteral or oral non-steroidal anti-inflammatory agent if no contraindication (i.e. gastritis, ulcer or renal impairment) 4. If no established pain plan: Morphine sulfate 0.1 mg/kg/dose IV q 2 hr. or 0.01–0.1 mg/kg/hr. continuous infusion or via PCA (doses above 0.1 mg/kg/hr. may be required but should be used with caution); alternative analgesics may be used in individual cases* 5. Reassess pain control at least twice daily and after every intervention; analgesics may be weaned as tolerated by decreasing dose, not by prolonging interval between doses; discuss analgesic changes with patient/family 6. Start oral opiates as soon as tolerated from a gastrointestinal standpoint, even if requiring IV opiates 7. Consider pain team consultation 8. Ceftriaxone 75mg/kg q 24 hr if febrile (prophylactic penicillin may be discontinued while on broad-spectrum antibiotics) 9. Continue prophylactic folic acid, if applicable 10. O_2 by nasal cannula as needed to keep O_2 saturation > 93% 11. Colace or laxative to prevent narcotic-induced constipation 12. See other Clinical Care Paths for acute chest syndrome, acute anemia crisis, stroke, priapism, if present 13. Avoid use of ice or cold packs	1. Taking oral fluids well and able to take all PO meds (e.g. prophylactic penicillin) if applicable 2. Adequate pain relief on oral analgesics 3. Afebrile >24 hr and negative cultures >24 hours if applicable 4. Resolution of any pulmonary symptoms or documentation of adequate oxygenation on room air

* These are the American Pain Society guidelines. Individual institutions, including Seattle Children's Hospital, may have differing practices.

Pathophysiology, Diagnosis, and Presentation

Individual risk factors for VOE pain include a higher WBC count, lower HbF, coexisting alpha thalassemia, and older age.[26] Physiologic factors that may lend to VOE include Hb polymerization, rheology of RBCs, cellular dehydration, RBC deformability and fragility, whole blood viscosity, WBC activation, endothelial factors, adhesion of RBCs to endothelium intimal hyperplasia, hemostatic factors, altered nitric oxide metabolism, and vascular factors.[8,11,22-26] Vessel occlusion results in ischemic/reperfusion injury and the release of multiple inflammatory mediators that activate nociceptors, evoking a pain response. Recurrent episodes lead to altered pain processing making assessment and management more complex. Diagnosis is based on a detailed qualitative description (typically two components: a deep fatiguing, unrelenting ache with a component of biting, gnawing or throbbing) and location (eFig. 90.5). The description is essential to help rule out other etiologies of pain, as there is no definitive test to differentiate sickle pain from other sources of pain. Physical findings can include swelling, warmth, erythema, and tenderness, but exams may be normal and it must be reenforced that patients can appear in no apparent distress. The role of laboratory and radiologic studies is to rule out other etiologies of pain. It is essential to perform quantitative pain assessments every several hours using a developmentally appropriate pain scale, followed by a reassessment of the pain plan. Pain assessment is difficult but pain is subjective and self-reports should be trusted. As pain becomes more chronic, the focus should move toward functional assessments.

EFIG. 90.5 Description of sickle cell pain. Depiction of the 6-year-old artist's sickle cell pain.

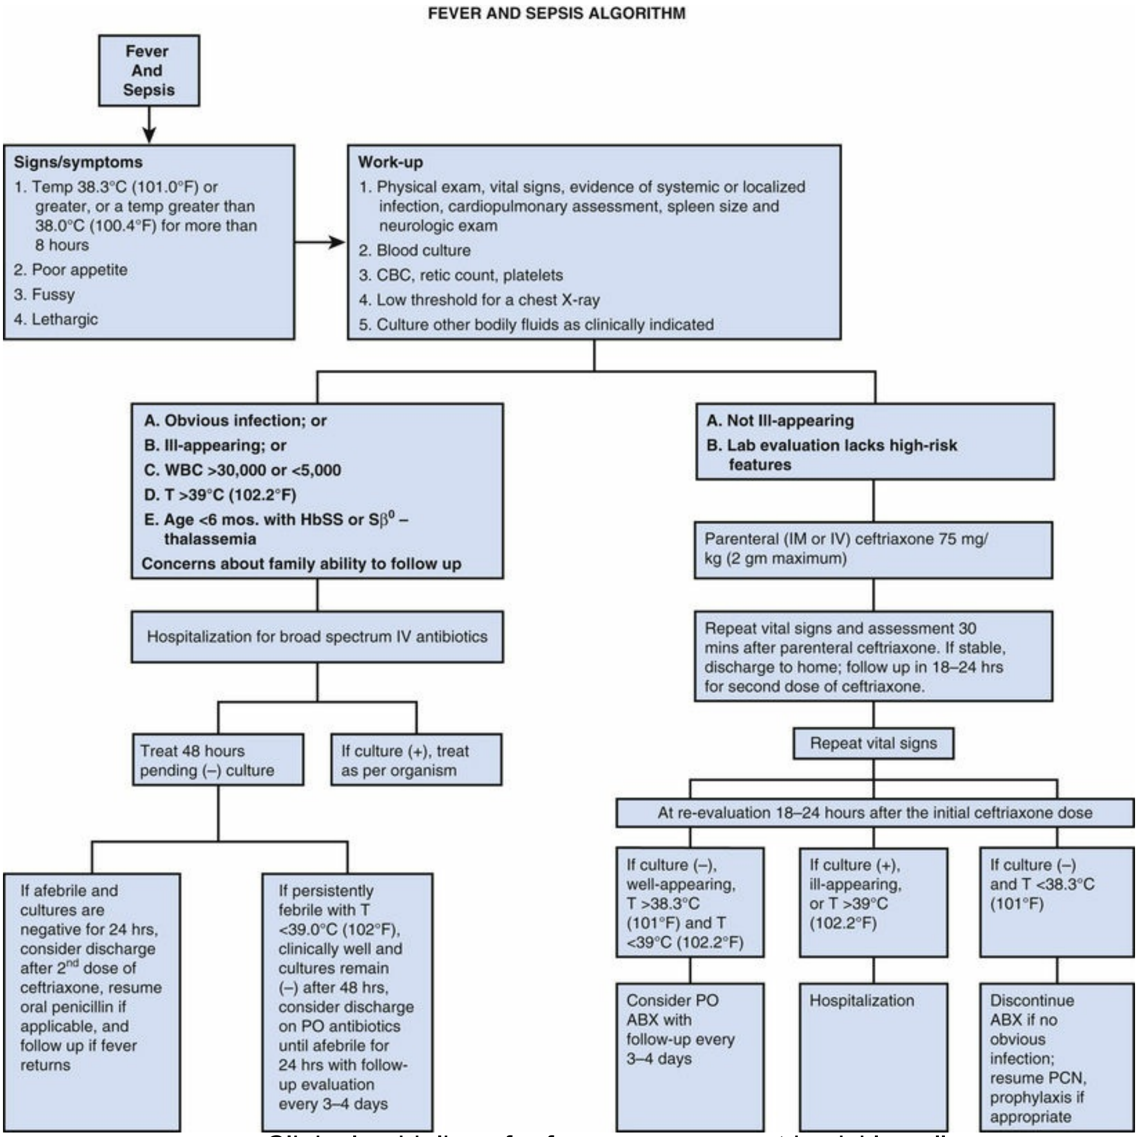
Management

See eFig. 90.2 for a detailed care plan and eFigs. 90.3 and 90.4 in the appendix for overviews of pain management.[18] An effective management strategy considers not only the underlying tissue damage and nociception but also the history of pain episodes, doses of medications required to achieve acceptable analgesia, baseline pain medications, history of tolerance, mental state, how the patient processes pain, coexisting depression, as well as the presence of anxiety or fear. A multimodal approach is outlined in eFigs. 90.3 and 90.4 but essential components include (1) environmental manipulation; (2) complementary methods; (3) addressing pathophysiology and triggers (fluids to maintain euvolemia, warmth, and NSAIDs to decrease CTT); and (4) adjunctive interventions such as physical therapy, ambulation, and incentive spirometry to maintain blood flow and prevent atelectasis and acute chest syndrome (ACS). After these issues have been addressed, providers may focus on opiates and additional medications.

Initial pharmacologic management of severe pain episodes includes the initiation of around-the-clock NSAIDs (many children will have resolution of pain with intravenous ketorolac[33]) followed by rapid and repeated doses of opiates (dosed every 20 minutes), transitioning to continuous infusion or patient-controlled analgesia (if developmentally appropriate).[30-32,34] Although the absence of pain is not a goal, the aim is to relieve pain and suffering and allow rest and health-promoting activities (incentive spirometry and ambulation to reduce the risk of ACS), while avoiding oversedation, which can contribute to the development of pulmonary complications. As cannabinoids have multiple effects on inflammation and neuropathic components of pain and can attenuate hyperalgesia, there is strong rationale for its use in SCD, although this remains controversial socially.[35] Use of L-arginine (a precursor of NO) has resulted in a 50% reduction in overall opiate use in SCD,[36] and there is increasing evidence for the use of glutamine.

Sepsis

Detailed sepsis care plans are presented in eFigs. 90.6 and 90.7.[18] Sepsis has historically been a major cause of morbidity and mortality in SCD. Strikingly, in the 1970s, 20% of SCD patients in the United States died before age 6 years, primarily from sepsis with encapsulated organisms, particularly *Streptococcus pneumoniae*.[5] With the initiation of universal newborn screening in the United States leading to early identification, early prophylactic penicillin, and education on the importance of fever response and immunizations, deaths from sepsis have plummeted.[37] Currently, the presence of a central line is the biggest risk factor for bacteremia.[38]



EFIG. 90.6 Clinical guidelines for fever management in sickle cell disease. (From Sickle Cell Disease. Critical Elements of Care. 5th ed. Seattle, WA: Center for Children with Special Needs, Seattle Children's Hospital; 2012. Available as a free download from http://cshcn.org/download-documents.)

APPROACH TO SEPSIS PREVENTION AND TREATMENT IN SICKLE CELL DISEASE

Prevention: immunizations	Routine childhood immunizations Ensure Hib and PCV-13 are up to date PPSV23 at age 2 years Meningococcal at 2 years or earlier per CDC guidelines
Prevention: prophylactic penicillin	125 mg PO BID until age 3 years 250 mg PO BID ages 3 years through 5 years
Emergent treatment: Antibiotics	• Evaluate all fevers of 38.3°C or higher, obtain blood and other clinically indicated cultures • Initiate parenteral antibiotics (ceftriaxone 75mg/kg) • Prophylactic penicillin should be held while patients are receiving these antibiotics Pneumococcus has a doubling time of 20 minutes in an asplenic person; thus a 2-hour delay can result in a 50-fold increase in bacterial burden
Cardiovascular support	Transfusion for hemodynamic instability.

EFIG. 90.7 Approach to sepsis prevention and treatment in sickle cell.

Pathophysiology and Etiology

The developmental timing of sepsis risk correlates with decreased splenic function due to infarcts leading to functional asplenia, which can be observed as early as 3 months. The resultant defects in cellular immunity, the alternate complement pathway and decrease in memory cells, and opsonizing antibodies will reduce clearance of encapsulated organisms. Children with SCD have a 100 to 400 times increased risk of bacteremia from encapsulated pathogens.

Management

The pathophysiology, diagnosis, and management of sepsis are presented in Chapter 111. Several aspects of sepsis that are unique to SCD are noted in eFig. 90.7.

Acute Chest Syndrome

Table 90.2 and eFig. 90.8 show detailed care plans.[18] ACS is clinically heterogeneous, and its definitions vary in the literature and among institutions, making comparisons of studies difficult. The most general definition is a new nonatelectatic infiltrate on chest radiograph in a patient with SCD, although others add requirements for fever, full lung segment involvement, or respiratory symptoms. ACS, the second leading cause of hospitalization in SCD and the leading cause of intensive care unit, admits among those 12 years and older.[39]

TABLE 90.2

Management of Acute Chest Syndrome

(1) Antibiotics	A cephalosporin to cover encapsulated organisms, particularly *S. pneumoniae*, and a macrolide such as *Mycoplasma* and *Chlamydia* are the most common infectious pathogens.
(2) Oxygen	Maintain saturations greater than 94%.
(3) Judicious fluid resuscitation	Maintain euvolemia while avoiding overly aggressive fluid resuscitation that may worsen cardiac and respiratory status due to a combination of severe anemia and decreased cardiac function.
(4) Prevention of atelectasis	Incentive spirometry (IS) has been shown to prevent development of ACS, thus IS and its alternatives.[142] Chest physiotherapy and ambulation may be of benefit once atelectasis and consolidation are present.[142,143] Bilevel positive airway pressure (BiPAP) or continuous positive airway pressure (CPAP) as a preventive measure is untested but appropriate as early intervention may prevent atelectasis and minute areas of collapse, preventing progression and the need for intubation.
(5) Pain management	Opiates should be carefully titrated to minimize splinting and allow IS, while minimizing respiratory depression (small opiate boluses before IS may be helpful). Unfortunately opiates are often withheld due to concerns of respiratory depression. In fact, pain relief can improve respiratory mechanics, significantly improving clinical status.
(6) Bronchodilators	Are indicated as asthma is common in sickle cell disease (SCD) and its presence increases the risk of acute chest syndrome (ACS), and a subset of patients respond independent of documented wheezing.[144]
(7) Corticosteroids	Use remains controversial as they tend to improve ACS but lead to rebound pain. Tapering of even pulsed steroids may reduce the rebound.[45-47]
(8) Transfusion	For multilobar disease, worsening pulmonary status despite conservative methods of treatment, or those who are critically ill.
(9) BiPAP or CPAP	For worsening pulmonary status, clinical decline, or those who are critically ill.

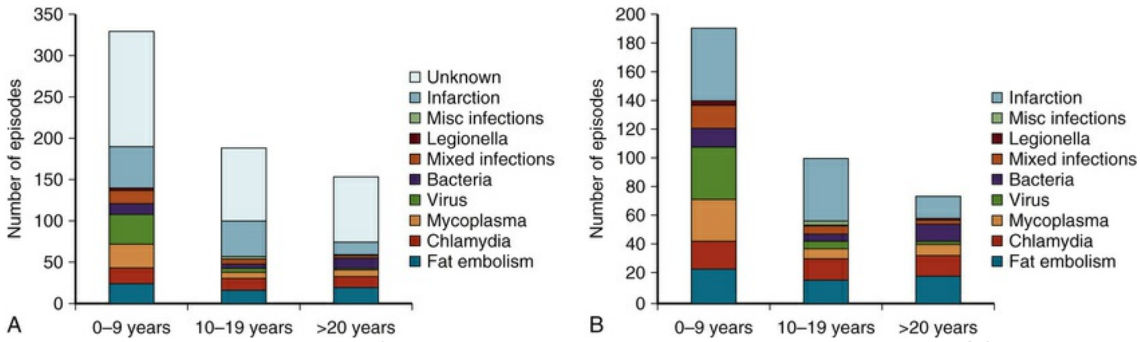
ACUTE CHEST SYNDROME

Diagnosis	Monitoring	Diagnostic (if not previously obtained)	Fluids, nutrition, general care	Medications/treatments	Discharge criteria
Definition: A new infiltrate on CXR in a patient with sickle cell disease.	1. Vital signs q 2–4 hr. 2. Continuous pulse oximetry. 3. Consider CR monitor. 4. Record daily input and output and weight.	1. CBC, diff., platelet count and reticulocyte count initially and daily until improving (compare with patient's baseline values). 2. CXR. Repeat for clinical deterioration looking for progression. May need serial CXRs. 3. Type and cross match (minor-antigen-matched if available, sickle negative, leukocyte depleted RBC) to have blood available. Obtain red cell extended phenotyping for sickle cell patients if not done previously (at a minimum type for RhD, Cc, Ee and Kell). 7. Blood cultures if T >38.2°C or history of recent fever. 8. Capillary or arterial blood gas and assessment by PICU team for severe illness.	1. Maintain "euvolemia." IV + PO 1–1.25 x maintenance. More fluid is appropriate only if patient is dehydrated or if insensible losses are increased (e.g. persistent fever). 2. Incentive spirometry x 10 breaths q 2 hr. during the day (0800–2200), if awake at night, and prior to all CXRs. 3. Encourage ambulation, activity.	1. Oxygen to maintain O_2 saturation >93%. 2. Ceftriaxone 75 mg/kg Q 24 hr. IV. (Prophylactic penicillin may be discontinued while on broad-spectrum antibiotics.) 3. Azithromycin 10 mg/kg PO x1, then 5 mg/kg PO QD days 2–5, or other macrolide antibiotic. 4. Chest physical therapy if consolidation is present. 5. Follow patients specific pain plan. If not available consider morphine 0.1 mg/kg IV q 2 hr. or 0.01–0.1 mg/kg/hr. continuous infusion or PCA for severe pain. Alternative analgesics (but not demerol) may be used in individual cases. Adequate pain relief is essential to avoid splinting improve respiratory dynamics that worsens respiratory status. 6. Consider round the clock bronchodilators, especially if patient has history of wheezing or asthma. Some patients benefit even if not clinically obstructed. 7. Consider use of BiPAP or CPAP if not improving with routine measures. 8. Consider red cell transfusion for progressive respiratory decline despite incentive spirometry and #1–6 above. Pain control and incentive spirometry are commonly under-utilized. Transfuse initially if severely ill. a. Simple transfusion to a HCT of 30% (no clear benefit to exchange transfusion). b. Exchange transfusion for patients with progressive disease and a Hct >27% or lack of improvement >36 hrs post simple transfusion. Target a Hct of 30% and Hb S or Hb S + C <30%. (May require transfer to ICU for erythrocytapheresis). Remove femoral or central venous catheters as soon as possible after exchange transfusion to reduce risk of thrombosis. 9. See other Clinical Care Paths for acute anemic crisis, stroke, priapism, if present. 10. Continue prophylactic folic acid, if applicable.	1. Off O_2. 2. Afebrile >24 hr and negative cultures for 24 hours (if applicable). 3. Good oral intake, able to take all oral medications including antibiotics. 4. Adequate pain relief (if needed) with oral analgesics. 5. Discharge instruction completed regarding home use of incentive spirometry while on opiates. 6. Follow-up plans coordinated with hematology service. CXR to establish new baseline in 2–3 months.

Modified from Mountain States Regional Genetic Services Network, 1996

EFIG. 90.8 Clinical guidelines for acute chest syndrome in sickle cell disease. (From Sickle Cell Disease. Critical Elements of Care. 5th ed. Seattle, WA: Center for Children with Special Needs, Seattle Children's Hospital; 2012. Available as a free download from http://cshcn.org/download-documents.)

ACS can progress in mere hours, resulting in a mortality rate of 1% in children (4% in adults), with most deaths occurring in children younger than age 3 years[40] (see Fig. 90.3). ACS accounts for 25% of all deaths in SCD.[40] Risk factors include a history of asthma, high baseline Hgb, and low HbF. Factors associated with mortality include a prior episode of ACS, development of respiratory failure within 48 hours of presentation, sepsis, and simultaneous presentation with pain.[40] Etiologies vary by age with multiple etiologic factors often present and include bacterial infections with typical and atypical organisms, viral infections, and fat emboli, as well as pulmonary infarction and hemorrhage (see also eFig. 90.9).[41] In addition, a functionally based etiology is chest or other extreme pain resulting in poor lung expansions and increased areas of atelectasis that then can lead to vasoocclusion and inflammation.



EFIG. 90.9 Etiologies of acute chest syndrome in sickle cell disease. Of 670 episodes, a specific etiology was identified in 38% of cases. In patients who had a complete workup, a specific etiology was identified in 70%. When a complete diagnostic workup was completed but no specific etiology was found, the etiology was classified as pulmonary infarction. (A) Etiology by age group. (B) The same data adjusted to include only patients who had a full diagnostic workup. Please note how prevalences vary with age. (Data from Vichinsky EP, Neumayr LD, Earles AN, et al. Causes and outcomes of the acute chest syndrome in sickle cell disease. National Acute Chest Syndrome Study Group. N Engl J Med. 2000;342:1855-1865.)

Presentation

ACS frequently occurs 2 to 3 days into a VOE. ACS should be suspected when there is fever, chest pain, cough, or other pulmonary symptoms; however, notably, there is no single pattern of signs and symptoms that predicts ACS, and up to 35% of patients will have a normal pulmonary exam.[40,42] As a result, there should always be a low threshold to obtain a chest radiograph to rule out ACS. Leukocytosis and significant drops in hemoglobin and platelets are common.[40] Significant morbidity is associated with ACS, including pneumothorax and empyema, and 14% of patients developed respiratory failure in one study.[41] Risk factors for respiratory failure include (1) extensive lobar involvement, (2) platelet count less than 199,000/μL, and (3) a history of cardiac disease.[41]

Management

Detailed care plans are presented in Table 90.2 and eFig. 90.8.[18] Management of ACS can be addressed in stages. Although there are not many randomized controlled trials to guide care of ACS,[43,44] suggestions for an approach to care are presented in Table 90.2. All patients should receive conservative care (highlighted in green in the table). The use of steroids (highlighted in yellow) deserves special attention. Although their use in ACS is controversial (see Table 90.2), due to the risk of rebound pain with steroid withdrawal a taper is indicated, even if only pulsed therapies are used (as in asthma or prior to extubation).[45-47] Transfusion (highlighted in red in the table) has been shown to significantly improve oxygenation and clinical status in ACS.[41] Although transfusion is usually effective at reversing ACS, because of the risks, including alloimmunization, transfusion is not part of initial management unless the patient is severely ill. Although 20% to 70% of patients with ACS are transfused, views differ on performing a simple transfusion targeting an Hgb of 10 g/dL or an exchange transfusion targeting the same Hgb while lowering the HbS to under 30%.[40,41] Both approaches improve oxygenation and are safe and

effective; however, exchange transfusion requires exposure to more donors, increases alloimmunization, is more time consuming, and may require central access in this population with increased thrombotic risk. Thus a simple direct transfusion is recommended for most situations.[48,49] The benefit of direct transfusion in ACS patients with a high Hgb (>9 g/dL) is less clear, as a minimal number of red cells can be transfused, and exchange may be more advantageous in this circumstance.

Although lacking formal studies, the use of bilevel positive airway pressure (BiPAP) or CPAP in an attempt to stave off intubation makes sense pathophysiologically. One small study determined that BiPAP use was successful in staving off respiratory failure,[50] whereas another found improvement in gas exchange and respiratory rate but not in hypoxemia or patient comfort.[51] There is no consensus as to when to intubate or the optimal ventilation strategy in ACS, thus patients are often treated as children with acute lung injury or acute respiratory distress syndrome (ARDS). For patients with refractory hypoxemia, both high-frequency oscillatory ventilation and venovenous extracorporeal membrane oxygenation have been successful.[52-54] A promising approach to ACS is to improve NO metabolism with inhaled NO or oral arginine, a precursor of NO.

Stroke

Clinical guidelines for stroke (eFig. 90.10) provide elements of a detailed care plan.[18] This section focuses on acute, clinically apparent cerebrovascular accident (CVA)–related to SCD; a detailed discussion of stroke can be found in Chapter 69. Before screening and prevention programs, 11% of children with HbS/S or HbS/β-thalassemia developed overt strokes (peak, 2 to 9 years), with another 20% to 35% having silent infarcts.[55-57] Risk factors include anemia, moyamoya, history of previous CVA, and abnormal transcranial Doppler (TCD) (discussed later).[58] Patients with HbS/C disease and other compound heterozygotic states do not have this significantly increased risk, although it may be higher than that in the general population. Strokes may be due to ischemia, hemorrhage, or thromboembolic events involving large, medium, and small vessels.

STROKE OR ACUTE NEUROLOGICAL EVENT

Diagnosis	Monitoring	Diagnostic (if not previously obtained)	Fluids, nutrition, general care	Medications/ treatments	Discharge criteria
Stroke or acute neurologic event in child with sickle cell disease	1. ICU admission first 24 hr and until stable 2. Vital signs, neuro checks q 2 hr 3. CR monitor 4. Continuous pulse ox 5. Record I + O, daily weight	1. CBC, diff, platelet count, reticulocyte count initially (compare with patient's baseline data) 2. Coagulation profile; consider evaluation for hypercoagulability 3. Blood and urine cultures if febrile 4. Type and cross-match (minor-antigen-matched if available (at a minimum RhD, Cc, Ee and Kell), sickle-negative, leukocyte-depleted RBC) for exchange transfusion (consider erythrocytapheresis) 5. Electrolytes initially and daily until stable 6. Emergent CT scan or MRI/MRA to exclude intracranial hemorrhage. MRI/ MRA when stable if not obtained initially 7. Consider CSF culture if febrile and no contraindication present 8. Consider hypercoagulation/ thrombosis evaluation	1. IV + po 1–1.25 x maintenance	1. Oxygen to maintain O_2 saturation >93% 2. Rx seizures if present 3. Rx increased intracranial pressure if present 4. Broad-spectrum IV antibiotics if febrile 5. If applicable and not on broad-spectrum antibiotics, continue prophylactic penicillin 6. Exchange transfusion or erhythrocyt-apheresis to a Hct of 30% and HbS ≤30%; remove femoral or central venous catheter as soon as possible to reduce risk of thrombosis 7. If exchange transfusion cannot be done acutely a simple transfusion with RBC to a Hct of 30% may be done but should be followed by and exchange transfusion when available. 8. Quantitative HbS after transfusion or at discharge	1. Clinically and neurologically stable >24 hr after transfusions 2. Afebrile >24 hr 3. Hematology and physical therapy follow-up organized

EFIG. 90.10 Clinical guidelines for acute stroke in sickle cell. (From Sickle Cell Disease. Critical Elements of Care. 5th ed. Seattle, WA: Center for Children with Special Needs, Seattle Children's Hospital; 2012. Available as a free download from http://cshcn.org/download-documents.)

Natural History

Prior to screening and preventive transfusion therapy, approximately 11% of patients with SCD had an overt stroke. Untreated, 50% have a recurrent stroke in the first 2 years, and 66% have recurrence within 9 years.[59] Maintaining the HbS under 30% reduces the recurrence rate to 10%, with many if these “resistant” patients having moyamoya.[60-62] Screening TCDs using a standardized approach identify patients with high cerebral vessel flow, associated with an excessively high stroke risk within 3 years.[63] Screening TCDs coupled with chronic prophylactic transfusion therapy have decreased the prevalence of stroke from 11% to 1%.[59]

Diagnosis

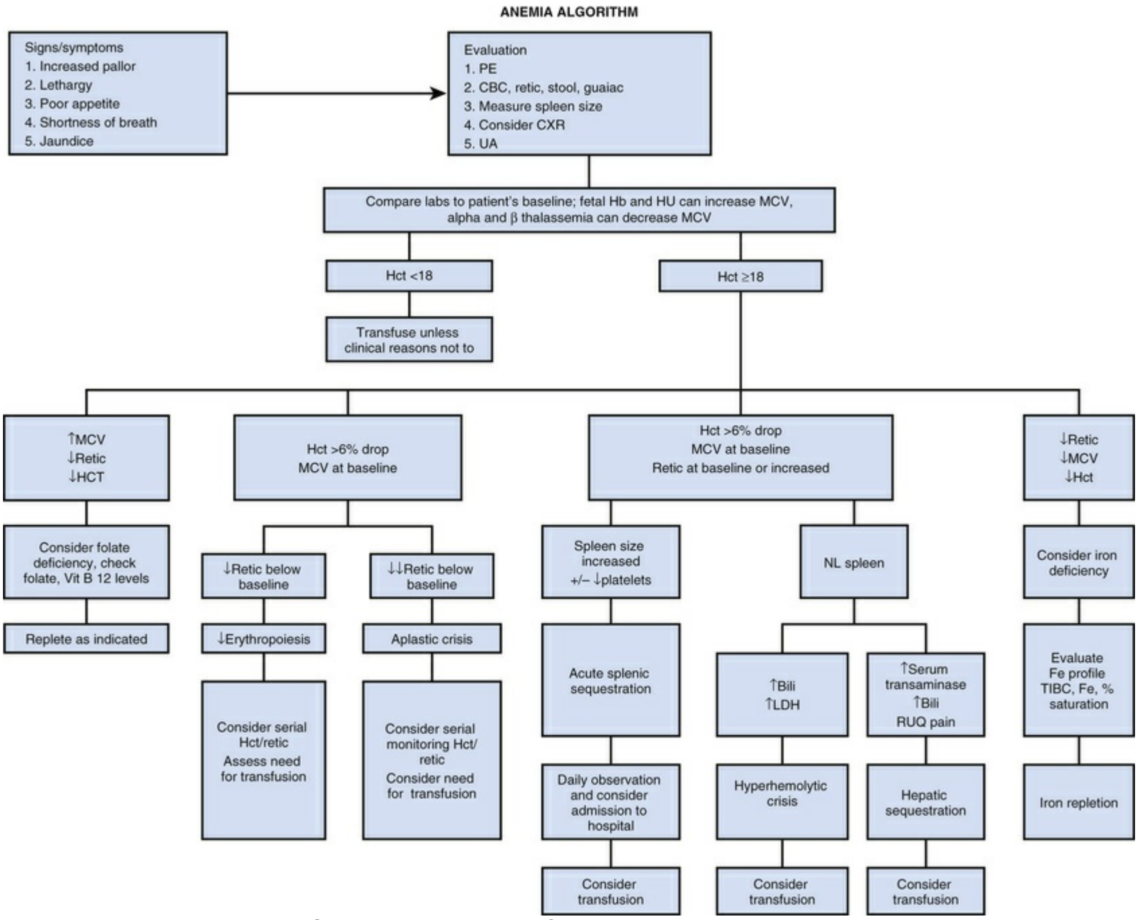
Although diagnosis is suggested by a history of acute neurologic changes and abnormalities on neurologic physical exam, magnetic resonance imaging (MRI) and magnetic resonance angiogram (MRA) confirm it. *Although an MRI/MRA is needed, it should never delay definitive therapy (transfusion or surgery) if stroke has been diagnosed clinically*.[64] Notably, headache and signs of increased cranial pressure are more common in hemorrhagic stroke (see Chapter 69). Neurosurgical intervention for a hemorrhagic lesion should never be delayed; thus an emergent noncontrast CT is obtained to immediately rule out any surgically amenable lesions, and MRI/MRA may be deferred. Other etiologies of childhood stroke must be considered and ruled out including infection, thrombosis (thrombosis panel and anticardiolipin antibodies), cardiac embolic disease, masses, and trauma with vascular damage.

Management

A detailed stroke management plan is provided in eFig. 90.10.[18] Acute care and monitoring are similar to that for other children with CVAs (see Chapter 69) except that emergent exchange transfusion is accepted as the standard of care in SCD.[17] The goal is an HbS under 30% and a final Hgb of 10 g/dL, which is most efficiently accomplished with exchange transfusion. Care must be taken to avoid hypotension with blood withdrawal during the exchange. Due to the importance of transfusing emergently, an initial direct transfusion followed by exchange transfusion to avoid delays in treatment may be appropriate, especially if the Hgb is under 8.[59] Seizures should be treated, but there is no role for seizure prophylaxis. Although tissue plasminogen activator (t-PA) has a role in non-SCD stroke, t-PA or anticoagulant therapy is not recommended in children, in part due to the different pathophysiology. Addition of low-dose aspirin is controversial but is started for some with concerns of an active cerebral vasculopathy.[65] Once stabilized, extensive evaluation by physical, occupational, and speech therapy as well as a neurocognitive evaluation is essential to define new postevent baselines and guide future needs.

Aplastic Crisis

An approach to evaluation and care is provided in eFig. 90.11.[18] An acute worsening of baseline anemia (by 1 to 2 g/dL of Hgb) associated with decreased reticulocyte count (typically <1%) suggests aplastic crises and is caused by acute infection such as parvovirus B19. Sickle RBCs survive 10 to 14 days (versus 60 to 100 days for normal cells); thus patients are dependent on a significantly increased reticulocyte production and any decrease can lead to a transient red cell aplasia with rapid development of a profound anemia. Monitoring of Hgb (both absolute and compared with the individual's baseline), reticulocyte count, and cardiovascular status is essential. Most parvovirus B19 infections will spontaneously resolve. However, intravenous gamma globulin should be considered to hasten viral clearance if reticulocytopenia persists. Transfusion may be required if the patient demonstrates hemodynamic instability and may be considered if the hemoglobin acutely falls more than 2 g/dL. Profound anemia or cardiac compromise may require a slow transfusion (2 mL/kg/hr), possibly with diuretics, or even exchange transfusion to avoid congestive heart failure.



EFIG. 90.11 Clinical guidelines for acute anemia in sickle cell disease. (From Sickle Cell Disease. Critical Elements of Care. 5th ed. Seattle, WA: Center for Children with Special Needs, Seattle Children's Hospital; 2012. Available as a free download from http://cshcn.org/download-documents.)

Splenic Sequestration

An approach to evaluation and care is presented in eFig. 90.12.[18] Sequestration is characterized by an acutely enlarging spleen with an Hgb more than 2 g/dL below an individual's baseline value. Mild to moderate thrombocytopenia may also be present. Splenic sequestration occurs in 10% to 30% of children with SCD, most commonly between the age 6 months and 3 years, often following a febrile illness. Abdominal pain, nausea, and vomiting are common, and severe episodes of sequestration may progress rapidly to cardiovascular collapse and death.[66] Transfusion is indicated when signs of cardiovascular instability are present and, as with aplastic crises, caution should be taken to avoid contributing to congestive heart failure. If the patient is transfused, it is important to be aware that with transfusion some patients release RBCs from their spleen, resulting in an unexpectantly high Hgb. Care must be taken not to overshoot the desired target, avoiding an Hgb of over 11g/dL. Though rare, emergent splenectomy may be required. Elective splenectomy is indicated for recurrent episodes of sequestration with cardiovascular compromise.

PRIAPISM

Diagnosis	Monitoring	Diagnostic (if not previously obtained)	Fluids, nutrition, general care	Medications/treatments	Discharge criteria
Stuttering priapism: under 2 hrs at a time, may be recurrent Persistent: over 2 hrs continuously	1. Vital signs q 2–4 hr 2. Record I+O, daily weight 3. CR monitor and continuous pulse ox if receiving parenteral narcotics	1. CBC, diff, platelet count, reticulocyte count initially (compare with patient's baseline data) 2. Urinalysis and urine culture 3. Blood culture if febrile; consider other cultures (e.g. CSF) as indicated	1. IV fluids: 10 cc/kg over 1 hr, then IV + po = 1.25–1.5 x maintenance 2. Encourage ambulation and voiding 3. Offer warm packs or hot shower/bath if available 4. Never use ice or cold packs 5. Incentive spirometry - 10 breaths q 2 hr 0800–2200 and when awake if on parenteral narcotics 6. NPO if surgical procedure planned 7. Observe for severe headache or neurologic signs or symptoms (some suggest increased risk of stroke)	1. Urology referral urgently if priapism persists more than 2 hrs 2. Consider pseudoephedrine <2 yr 4 mg/kg/ day split q 6 hr po; 2–5 yr 15 mg q 6 hr po; 6–12 yr 30 mg q 6 hr po, >12 yr 60 mg po q 6 hr 3. Strongly consider arranging aspiration and irrigation with epinephrine (1:1,000,000) after 2 hrs. Notify urology within 2 hrs of onset of priapism with goal of performing procedure before 6 hours. All attempts should be made to do this within 12 hrs of onset. This can be done with local and a benzodiazepine, conscious sedation or general. Repeat procedures may be required. 4. Pain control a. Ibuprofen 10 mg/kg po q 6 hr or other anti-inflammatory agent if no gastritis, ulcer or renal impairment present b. Morphine 0.05–0.1 mg/kg IV q 2 hr or 0.01–0.1 mg/kg/hr continuous infusion or PCA pump (max total dose) for severe pain 5. Broad-spectrum IV antibiotics if febrile 6. If applicable, continue prophylactic penicillin (if not on broad-spectrum antibiotics) and folic acid 7. O_2 by nasal cannula if needed to keep pulse ox >93% 8. See other clinical care paths for acute chest syndrome, acute anemic crisis, stroke, if present	1. Priapism resolving (complete detumescence may take 1–2 wks) 2. Taking oral fluids well and able to take po medications (e.g. prophylactic penicillin) if applicable 3. Adequate pain relief on oral analgesics 4. Afebrile ≥ 24 hr 5. Adequate oxygenation on room air

Modified from Mountain States Regional Genetic Services Network, 1996

EFIG. 90.12 Clinical guidelines for priapism in sickle cell. (From Sickle Cell Disease. Critical Elements of Care. 5th ed. Seattle, WA: Center for Children with Special Needs, Seattle Children's Hospital; 2012. Available as a free download from http://cshcn.org/download-documents.)

Pulmonary Hypertension

Pulmonary artery hypertension (PAH) confirmed by right heart catheterization affects approximately 6% to 11% of adults and children with sickle cell disease. Elevated tricuspid regurgitation velocity indicating PAH occurs in approximately 30% of adults with sickle cell disease and is associated with increased mortality.[67] With approximately 100,000 people with SCD in the United States, this translates into about 30,000 cases of PAH, making sickle cell the leading cause of PAH nationally. Although there has been concern for overdiagnosing PAH in SCD by an elevated tricuspid regurgitant jet velocity (TRV) on transthoracic echocardiography (TTE), it is increasingly understood that adults with estimated PAPs greater than 25

mm Hg or a tricuspid regurgitation velocity jet velocity (TR jet) of greater than 2.5 m/sec have a strikingly higher mortality rate.[12,68,69] Thus it is essential to have a significantly lower threshold for aggressive intervention for PAH in the hemoglobinopathy patient than in others.

Pathophysiology and Etiology

Multiple pathways contribute to PAH in the sickle cell patient. Hemolysis leads to nitric oxide dysregulation, vascular dysfunction, injury, and inflammation, which can ultimately lead to PAH.[8,12,70] Progressive increases in pulmonary vascular resistance related to decreases in nitric oxide (NO) availability and dysregulation ultimately lead to right ventricular failure and decreased cardiac output. The 2014 American Thoracic Society Guidelines for PAH in SCD define PAH as a resting mean pulmonary arterial pressure equal to or exceeding 25 mm Hg.[67] Frequently confounding factors in the PH of SCD include (1) hypoxic PAH due to the high incidence of enlarged tonsils, obstructive sleep apnea, asthma, and chronic lung disease; (2) arterial obstructive PAH secondary to increased coagulation and embolic disease; and (3) pulmonary venous hypertension due to cardiomyopathy. Contributing to the high morbidity in SCD are the protean manifestations of mild pulmonary hypertension (>25 mm Hg). The majority of patients with SCD and PAH will be asymptomatic or have mild decreases in exercise tolerance (eg, 6-minute walk) yet have a 10-fold increased risk of death.[69] Increased mortality has been associated with a TRV of 2.5 m/second or higher in adults (10 times greater mortality risk), NT-pro-BNP levels of >160 in adults (at least 5 times greater mortality risk), and pulmonary artery pressure >25 mm Hg on right ventricular heart catheterization in adults. Sufficient data in children are lacking, thus some suggest using the American Thoracic Society (ATS) adult criteria, though this is controversial as it has be suggested that there is no increased risk of death within 3 years of diagnosis.[71]

Diagnosis

Though cardiac catheterization is the gold standard for determination of PAH, it is invasive and expensive. Catheterization is reserved for a subset of the patients initiating PAH-specific therapies.[67] Current diagnostic recommendations include TRV as measured by echocardiogram, using a TRV of 2.5 m/sec as a criterion for diagnosis.

Management

Although there is minimal evidence for specific therapies in the treatment of PAH in SCD, a multitiered approach is accepted by many: (1) identifying and reversing factors potentially contributing to PH (eg, tonsil- and adenoidectomy, bilevel positive airway pressure [BiPAP] or continuous positive airway pressure [CPAP], and nighttime O_2 if contributing to obstructive sleep apnea [OSA]), (2) optimizing of sickle cell specific care (eg, hydroxyurea or chronic transfusions), and (3) applying PH-specific therapies. Hydroxyurea (HU) is the first-line treatment for SCD-specific care, as it decreases hemolysis and sickle cell formation, it decreases ACS and VOE (both of which are associated with acute increases in pulmonary pressures), and it is recommended for most adults and most pediatric patients. Chronic transfusion therapy is the second-line therapy for PAH in SCD, reserved for those who do not

respond to HU. Although controversial and lacking data, the mortality risk of PAH is felt to outweigh the potential side effects of transfusion therapy. For those with right heart catheterization defined PAH additional therapies are recommended. For those with venous thromboembolism and no additional risk factors for bleeding, indefinite anticoagulant therapy is recommended. Targeted PAH therapies such as prostacyclin agonists (eg, iloprost), endothelin receptor antagonists (eg, bosentan), soluble guanylate cyclase stimulators (eg, riociguat), or phosphodiesterase-5 inhibitors (eg, tadalafil), and other PH therapies should be tried, but limited data exist for their use (see also Chapter 56). Despite considerable enthusiasm for the use of sildenafil, a randomized controlled trial (RCT) was halted early do to an increase in VOE in the treatment group, emphasizing caution in applying accepted PH therapies to SCD.[72]

A mainstay of treatment of PAH in the ICU is inhaled NO (iNO), which provides both direct vasodilation of the pulmonary vasculature and simultaneous reversal of the underlying disruption in NO metabolism. The major challenge with iNO is the development of rebound PAH on discontinuation of therapy and difficulty in administration, thus driving a focus on alternative therapies. Oral arginine, a precursor of NO, was shown to reduce PAP within 5 days of therapy in a small number of patients with SCD and PHTN[73] and is being further investigated.

Multiorgan Failure

Multiorgan failure syndrome is defined as severe pain associated with failure of at least two of the following organs: liver, lung, and kidney. It is often associated with severe pain in patients with previously mild disease and a relatively high Hgb.[74] Widespread vasoocclusion is thought to be responsible, though data are lacking. Patients present with an atypically severe VOE, fever, and sudden deterioration including a drop in Hgb and platelets, diffuse encephalopathy, and rhabdomyolysis. Death has been reported in up to 25% of patients.[75] Exchange transfusion should be considered early and can result in rapid recovery of organ function as well as survival. Antibiotics are often used, though many patients are culture negative. There are isolated reports of success with NO or plasma exchange in those with transfusion-resistant disease, consistent with the idea that this may represent a thrombotic thrombocytopenia (TTP)–like state.[76]

Renal Conditions

Renal injury is caused by sickling in the renal microvasculature.[77,78] The normal renal medullary environment is hypoxic, acidotic, and hypertonic. In the face of sickle cell disease and sometimes even the sickle trait, these conditions lead to sickling, increased viscosity, and ischemia, causing damage to the renal medulla such as segmental scarring and interstitial fibrosis, which can progress to infarction and necrosis including papillary necrosis:

1. Hyposthenuria is an inability to concentrate urine. It is critical to remain aware of this condition in the ICU, as the production of dilute urine cannot be used as a marker for being euvolemic, and patients are prone to dehydration, leading to vasoocclusive episodes.

2. Hematuria can range from micro- to gross hematuria associated with papillary

necrosis due to medullary infarction. Conservative management with bed rest, IV fluids, and maintenance of high-urine output to avoid the development of clots usually suffices. Transfusions may be needed if blood loss is significant. Vasopressin has been used with some success, as has ε-amino caproic acid, though the latter should be used with caution as it can lead to clot. If recurrent transfusions are required or bleeding becomes life threatening, resection of the involved region may be indicated.

3. Tubule dysfunction may occur, including an incomplete renal tubular acidosis worsened by the hyposthenuria, and hyperkalemia secondary to impaired urinary potassium excretion, the use of potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, or β-blockers.

4. Chronic renal failure is associated with glomerular injury and proteinuria and can include nephrotic syndrome. End-stage renal disease develops in 40% of patients with nephrotic syndrome, thus persistent proteinuria is an indication for an in-depth evaluation. Risk factors include hypertension, hematuria, proteinuria, and worsening anemia. Although there is no clear cure, angiotensin-converting enzyme inhibitors can reduce the proteinuria, and NSAIDs should be avoided. Worsening anemia can be treated with erythropoietin, though sickle cell patients often need higher doses than others.

Iron Overload

Unlike thalassemia, the iron overload of sickle cell is primarily related to transfusion.[79] Sickle cell and thalassemic patients show different patterns of iron deposition, and the heart accumulates iron far less readily in SCD. The acute management in the ICU is similar and is discussed in the "Thalassemia" section.

Sleep Conditions

Children with SCD have a higher prevalence of obstructive sleep apnea (OSA) than the general pediatric population (20%-41%), likely due to greater airway crowding related to increased tonsillar, adenoid, and cervical node size.[80-82] Sleep disturbances and OSA contribute to decreased oxygen saturation levels, further increased endothelial dysfunction and inflammatory process leading to increased VOE, decreased pulmonary function, increased risk of pulmonary hypertension, and depression.[82,83] Although tonsillectomy and adenoidectomy may be helpful in OSA, noninvasive ventilation with CPAP or BiPAP may be necessary and may be initiated in the pediatric intensive care unit (PICU). CPAP has been well tolerated in SCD and shown to improve sleep and cognitive function.[84]

Depression and Suicide

With recurrent pain and complications that can occur without warning, it is not surprising that anxiety and depression are increased in patients with SCD.[85,86] Interestingly, rates are higher than in cystic fibrosis, spina bifida, or diabetes, with 49% having anxiety symptoms in one study, and the risk of suicide in adults is increased.[86-89] Anxiety and depression as well as suicidal ideation if present should be addressed in the acute care setting.

Surgery and Anesthesia

A detailed care plan for the sickle cell patient scheduled for surgery and anesthesia is provided in eFig. 90.13.[18] Major surgery in sickle cell patients is associated with increased perioperative risks including VOE pain, acute chest syndrome, and death, but these can be minimized with specific perioperative care. Preoperative direct transfusion targeting an Hgb of 10 minimizes these risks and is preferred over an exchange transfusion in most cases because of the exposure to fewer units of blood and less alloimmunization.[90,91] Communication and coordination between the anesthesiologist, surgeon, and hematologist are essential, and institutions are encouraged to have a standard perioperative care plan for SCD. Most patients are admitted overnight following surgery for oxygen, pain management to assure the ability to deep breathe and perform incentive spirometry, and monitoring for pain and pulmonary complications, even if cleared to return home from a surgical standpoint. Because of poor compliance with incentive spirometry, the use of BiPAP in the immediate postoperative period may be beneficial.[92] Specific recommendations should be followed (see eFig. 90.13).

GENERAL ANESTHESIA AND SURGERY

Pro-op evaluation	Pre-op transfusion and pulmonary care	Intraoperative	Post-operatives
• Baseline CXR, pulse ox CBC, retic, U/A • Consider pulmonary function tests and/or ECHO for patients with prior history of acute chest syndrome, suspicion of chronic lung disease or decreased exercise performance • Coordination of peri-operative plan with hematology, surgery and anesthesia	• Patient typically admitted the day before for transfusion and hydration while NPO • Simple transfusion targeting a Hct of 30–33% should be strongly considered for all children with Hb SS or $S\beta^0$-thalassemia prior to any procedure requiring general anesthesia • Surgery without pre-op transfusion in children with HbS/S and $S\beta^0$-thalassemia may be considered in selected cases non- or minimally-invasive procedures (e.g. PE tubes or MRI/MRA). Note: tonsillectomy and/or adenoidectomy is **not** considered a minor procedure. Recommendations for patients with Hb S/C and $S\beta^+$-thalassemia vary. In general, transfusion is not required for smaller procedures such as tonsillectomy and/or adenoidectomy, but transfusion is required for abdominal surgery. Due to a high baseline HCT, these patients often require exchange transfusion. • Use antigen-matched if available, sickle-negative, leukocyte-depleted PRBC (at a minimum RhD, Cc, Ee and Kell) • Practice incentive spirometry or developmentally appropriate substitute (e.g. bubbles) • If history of obstructive disease, start steroid inhaler 3 days before and scheduled albuterol the night before surgery • IV hydration 1–1.25 x maintenance while NPO before procedure. Hold while receiving blood transfusion.	• Minimum 50% O_2 with anesthetic agent • Avoid hypoxia (continuous pulse ox), hypercarbia, or hyperventilation • Avoid tourniquets	• O_2 by nasal cannula at 2 L/min and continuous pulse ox even if O_2 saturations are high. Continue O/N and assess the next day. Maintain saturations >93%. • Document O_2 saturations on room air intermittently to screen for increasing O_2 need. • Encourage early ambulation, activity • IV + po 1–1.25 x maintenance. Avoid excessive hydration, which may precipitate acute chest syndrome. • Strict adherence incentive spirometry: 10 breaths q 2 hr while awake. Use of pain medication before this may be useful.

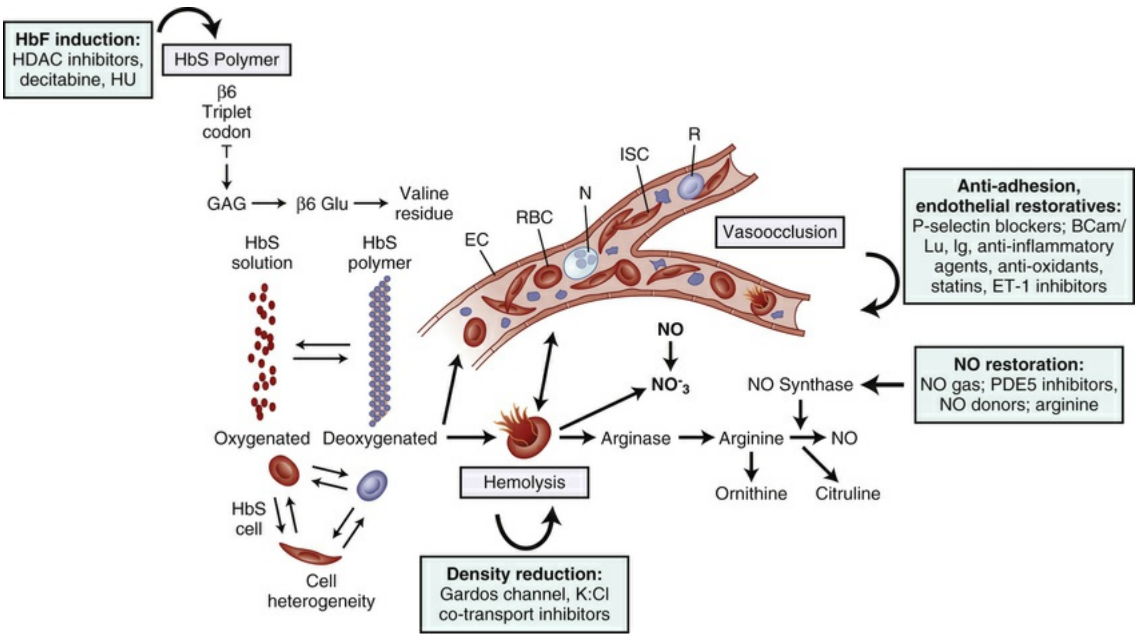
Disease-Modifying Therapies and Interventions

The impact of public health policy and family education focused on prevention, early detection, and early intervention cannot be overstated. The preventive measures have led to dramatic improvement in morbidity, mortality, and quality of life. Additional therapies for prevention or the long-term treatment of complications targeting specific mechanisms involved in the pathophysiology of SCD follow (see eFig. 90.14 for an overview).



EFIG. 90.14 Interventions targeting the pathophysiology of sickle cell disease. Summary of multiple interacting steps contributing to the pathophysiology of SCD, and some of the interventions being investigated. (From Steinberg MH. Sickle cell anemia, the first molecular disease: overview of molecular etiology, pathophysiology, and therapeutic approaches. Sci World J. 2008;8:1295-1324. Figure generously provided with permission from Dr. Martin Steinberg, Boston University School of Medicine.)

Hydroxyurea

Although hydroxyurea is not an acute intervention, the intensivist should be aware that most SCD patients should be on hydroxyurea.[17,93-95] Hydroxyurea ameliorates sickle cell disease by decreasing pain, ACS episodes, and transfusion needs while increasing hemoglobin, quality of life, and life span.[17,93-95] Originally used in SCD to stimulate HbF production, the primary clinical benefits may stem from the relative leukopenia induced by this oral chemotherapeutic as well as decreasing hemolysis (see “Pathophysiology” and “Etilogy,” presented earlier). When assessing complete blood counts (CBCs), clinicians should remain aware that hydroxyurea can decrease all cell lineages and lead to a red cell macrocytosis with mean corpuscular volumes (MCVs) into the 115 range. There is no recommendation to routinely discontinue

hydroxyurea during acute illness or hospitalizations. The intensivist should be aware that hydroxyurea can cause a transaminitis and is renally cleared so it should be adjusted or held with hepatic or renal compromise, or with clinically significant cytopenias.

Transfusion

Though a mainstay of therapy, guidelines for transfusions in SCD are complex and vary by indication. The reflective tendency to transfuse SCD patients should be avoided. Because of alloimmunization and other risks, attempts should be made to avoid transfusion unless there is a clear clinical indication, and consultation with hematology is advised. Table 90.3 summarizes guidelines, and additional information is provided in specific sections presented earlier.[17,96-100] General guidelines for transfusion are provided in Chapter 93 for general information regarding blood transfusion. SCD-specific issues follow.

TABLE 90.3

Indications for Transfusion in Sickle Cell Disease

	Duration	Consensus	Method	Goal[a]
Stroke, acute	Single	+	Ex	HbS <30%
Stroke, ongoing care	Chronic	+	Either	HbS <30%
High-velocity TCD	Chronic	+	Either	HbS <30%
ACS, initial episode	Single	+ (for severe or progressive ACS)	Dir > Ex	Hgb 10
ACS, recurrent	6-12 months	+	Either	
PHTN	Chronic	+	Either	
Multiorgan failure	Single	+	Ex	
Major surgery	Single	+	Dir	Hgb 10
Acute anemia	Single	+	Dir	
Recurrent spleen sequestration	Chronic	+		
Sepsis/meningitis	Single	+	Dir	
Severe chronic pain	6-12 months	+		
Congestive heart failure	Chronic	+		
Silent infarct	Chronic	−		
Pregnancy		−		
Anemia/renal failure	Chronic	−		
Leg ulcers	6-12 months	−		
Severe growth delay		−		
Severe eye disease		−		
Priapism		−		

[a]Goal of transfusion if a consensus has been reached.

Dir, direct; *Ex*, exchange; *Hb*, hemoglobin type; *Hgb*, hemoglobin concentration; +, consensus reached; −, consensus not reached.

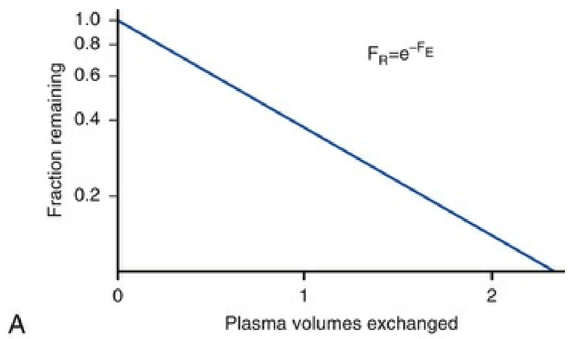
Choice of Product

Packed RBCs should be leuko-depleted to minimize febrile reactions and alloimmunization. Although transfusion from sickle trait donors is safe and effective, HbS-negative blood should be requested as it complicates assessment of posttransfusion HbS levels. An extended cross-match for antigens of clinical significance that vary between racial groups should always be requested, as it reduces alloimmunization and should include Rh (Cc, D, Ee) and Kell in addition to ABO.[17,101,102] The intensivist must be aware that matching or finding compatible units for highly immunized patients may take considerable time, thus a type and cross should be sent well before blood is needed, and in some emergencies extended

matching may need to be forgone. Unlike the protocol used for patients with hematologic malignancies, there is no need for blood product irradiation or CMV negative selection unless the patient is waiting for or undergoing transplant.

Type and Goals of Transfusion

Goals of transfusion in SCD include increasing O_2 carrying capacity or decreasing HbS. Different modes of transfusion can be utilized to reach the intended goal. The target hemoglobin concentration or HbS percentage varies with indication (see Table 90.3), but in most cases the final Hgb should never be higher than 11 because whereas oxygen carrying capacity increases, O_2 delivery may fall.[103] Formulas for calculating blood volumes for routine and exchange transfusions are available (eFig. 90.15). In many cases, a direct transfusion is as effective as an exchange transfusion and is therefore preferred to minimize alloimmunization. One significant exception is acute stroke, where an automated exchange (erythrocytapheresis) to bring the HbS level down quickly while raising the Hgb is standard of care.[17] This requires either two large-bore peripheral IVs (which can be difficult in some patients) or a pheresis-compatible central line that can accommodate flow rates and pressures required during red cell erythrocytapheresis (RCE). Good coordination and communication about the specific line to be placed should occur with the blood center or program operating the pheresis machine. Children under 10 kg may not be able to tolerate automated RCE and may require a manual exchange transfusion, which requires significant nursing time to complete but can be effective and requires only one large-bore peripheral IV. A brief summary table of recommendations for mode of transfusion is provided for reference (see Table 90.3).



(A) Formula to calculate how many blood volumes must be exchanged to obtain a specified decrease in HbS (assuming no change in Hgb). For example, 1 to 1.5 volumes must be exchanged to decrease HbS from 90% to 100% to less than 30%. (Figure generously provided with permission from Dr. Thomas Price, Puget Sound Blood Center.)

$$V_{rbc} = Hct_i \times TBV$$

V_{rbc} = Total red cell volume (ml)

Hct_i = Initial hematocrit

TBV = Total blood volume (ml)

B

(B) Formula to determine total red cell volume. (From Wayne AS, Kevy SV, Nathan DG. Transfusion management of sickle cell disease. Blood. 1993;81:1109-1123.)

$$V_{ex} = V_{rbc} \times V_d$$

V_{ex} = Volume of blood to exchange

V_{rbc} = Total red cell volume (ml)

V_d = Desired blood volumes to exchange based on panel A

C

(C) Formula to determine what volume of packed red blood cells is required for exchange.

$$U_{rbc} = \frac{V_{ex}}{Hct_u \times V_u}$$

U_{rbc} = Number of units of blood required

V_{ex} = Volume of blood to exchange

Hct_u = Hematocrit of a unit of blood

V_u = Volume of a unit of blood

D

(D) Formula to determine how many units of blood are required for exchange. Entire units should be used, so round up or down depending on the clinical situation. Note that for small children an additional unit may be required to prime the circuit. Please check with your local erythrocytapheresis to determine if this is necessary.

$$HbS_f = \left[1 - \frac{Hct_u \times V_{tf}}{(Hct_i \times TBV) + (Hct_u \times V_{tf})}\right] \times HbS_i$$

HbS_f = Final percentage of HbS, after direct transfusion
HbS_i = Initial percentage of HbS, before direct transfusion
Hct_u = Hematocrit of a unit of blood
V_{tf} = Volume of packed red cells transfused (ml)
Hct_i = Initial hematocrit
TBV = Total blood volume (ml)

E

(E) Formula to determine the decrease in HbS upon direct transfusion. (From Wayne AS, Kevy SV, Nathan DG. Transfusion management of sickle cell disease. Blood. 1993;81:1109-1123.)

EFIG. 90.15 Approach to exchange transfusion. Details of how to perform an exchange transfusion vary depending on patient size, IV access, available resources, and institutional biases, but basics are outlined in the following: The management of sickle cell disease. Bethesda, MD: National Heart, Lung, and Blood Institute; 2002. If available, erythrocytapheresis or automated red cell exchange is preferred by most due to its speed, efficiency, and ease. Modern machines require the patient weight, Hgb, and estimated percent of HbS, in addition to the desired postexchange Hgb and HbS, and the amount of blood required (calculated below). Although many formulas are available to aid in performing exchange transfusions, several simple stepwise calculations can be used. Determination of the volume of red cells to exchange depends on the initial and desired percent of HbS and is based on the first-order decline in HbS during an exchange (panel A). Given the patient's total blood volume (varying from 65-80mL/kg depending on age [see also Chapter 93]) the patient's red cell volume is calculated (panel B), and using data from panel A, the total volume of red cells needed is determined (panel C). From this, the number of units of blood required is determined (panel D). Even though exchange transfusion is optimal for rapidly lowering the percentage of HbS, direct transfusion reduces HbS dilutionally, the extent of which can be calculated (panel E). When erythrocytapheresis is not available, direct transfusion in conjunction with a partial manual exchange transfusion can significantly lower the percentage of HbS.

Hematopoietic Stem Cell Transplantation

Hematopoietic stem cell transplantation (HSCT) remains the one cure for SCD, and the role of the ICU is supportive care posttransplant (see Chapter 95). Because of striking results with a matched sibling transplant after a myeloablative-conditioning regime (85% event-free survival and a 94% overall survival with approximately 10% graft failure and 12% to 20% significant graft-versus-host disease [GVHD]) increasingly children with less severe disease are being transplanted.[104-108] Multiple SCD research transplant studies are available and address optimizing the conditioning regime, extending transplants to older patients, and using alternate donors (unrelated, cord blood, haploidentical).[106-109]

Gene Therapy

Modification of autologous HSCs to correct the sickle mutation or add a normal gene avoids many of the problems of routine HSCT but remains experimental with a limited number of clinical trials (see "Thalassemia" presented later). Go to clinicaltrials.gov for currently open trials.

Induction of β-Like Chains

See the "Thalassemia" section for more detailed information on this topic.

Novel Therapies

The numerous pathophysiologic paths contributing to SCD are providing targets for novel therapeutics, too numerous to be reviewed here but discussed elsewhere.[110,111] Similarly, multiple mechanisms involved in the classic approach, such as induction of HbF, are actively being pursued.[112-114]

Thalassemia

Molecular Description and Epidemiology

In contrast to a single mutation being responsible for sickle cell and the mutant peptide directly leading to the pathophysiology, a textbook compendium of mutations can lead to thalassemia and it is the residual unpaired phenotypically normal globin chains that incite damage. The hallmark of thalassemia is an imbalance in the ratio of α- and β-chains, not necessarily a deficiency in chains. The distinction becomes important when one considers α-/β-thalassemia compound heterozygotes or duplicated (excess) globin genes. Gene deletions account for the majority of α-thalassemias, leading to quantum incremental changes in phenotype depending on whether one, two, three, or all four adult α-globin genes are missing. In contrast, the broad range of mutations that leads to β-thalassemia result in a continuum of clinical phenotypes. As with the sickle cell trait, the thalassemia trait is thought to provide increased fitness in malaria zones. The coexistence of α- and β-thalassemia in the same geographic regions leads to compound heterozygotes being common, resulting in a huge spectrum of disease and complicating diagnostics.

Laboratory and Diagnostics

Although the sine qua non of diagnostics is a microcytic anemia with the demonstration of an α- to β-globin chain imbalance, this is not practical for routine testing, thus most clinical laboratories rely on a variation of a thalassemia screen. The screen helps distinguish thalassemia from iron deficiency, and α- from β-thalassemia. Due to the wide range of defects and frequent mixed α- and β-thalassemia patients, it is impossible to state absolutes for diagnostic interpretation, and there should be a low threshold to consult with a hematologist. Components of the screen include (1) a complete blood count where emphasis is placed on the MCV, which is decreased in proportion to hemoglobin production, the RBC to assess the degree of compensation for the decreased cell size, the hemoglobin, and the smear; (2) a hemoglobin electrophoresis or high pressure liquid chromatography (HPLC) to quantitate normal and variant hemoglobins; (3) an inclusion body or Brilliant Cresyl Blue preparation to semiquantitatively assess excess β-like chains and distinguish α-

and β-thalassemia; and a (4) zinc-protoporphyrin or similar screen to exclude iron deficiency. α-Thalassemia results in excess β-like chains that form tetramers (β4: Hb H, γ4: Hb Barts) that precipitate in proportion to the number of missing α-genes, resulting in a positive inclusion body prep (Table 90.4). The diagnosis of β-thalassemia is less direct. Excess α-chains are less stable and degrade so no α-tetramers are detectable on electrophoresis or HPLC. Thus a microcytic anemia with negative inclusion body prep in the face of adequate iron is suggestive of β-thalassemia. Frequently β-thalassemia results in up regulation of HbA2 or HbF; thus the presence of either is suggestive of the diagnosis.

TABLE 90.4

Distinguishing Laboratory Features of α- and β-Thalassemias

Diagnosis[a]	BCB Prep[b]	HbA_2[c]	HbF	HbH	Hb Barts in Newborn[d]
Normal	−	nl	nl	nl	−
α-Thalassemia	+	nl	nl	nl or ↑	+
β-Thalassemia	−	nl or ↑	nl or ↑	nl	−

[a]All forms of α- or β-thalassemia are pooled; specific results will vary.

[b]Brilliant cresyl blue *(BCB)* or inclusion body prep. Results vary by lab, but this can be done semiquantitatively and increases with the degree of α-thalassemia.

[c]HbA_2 results vary depending on laboratory method.

[d]Hb Barts increases with the degree of α-thalassemia.

Table shows typical results; exceptions occur.

This can be negative when a one α-globin deletion is present (silent carrier). This assay is unreliable in the presence of other hemoglobins (eg, HbS or HbE). This can be negative when α- and β-thalassemia are simultaneously present.

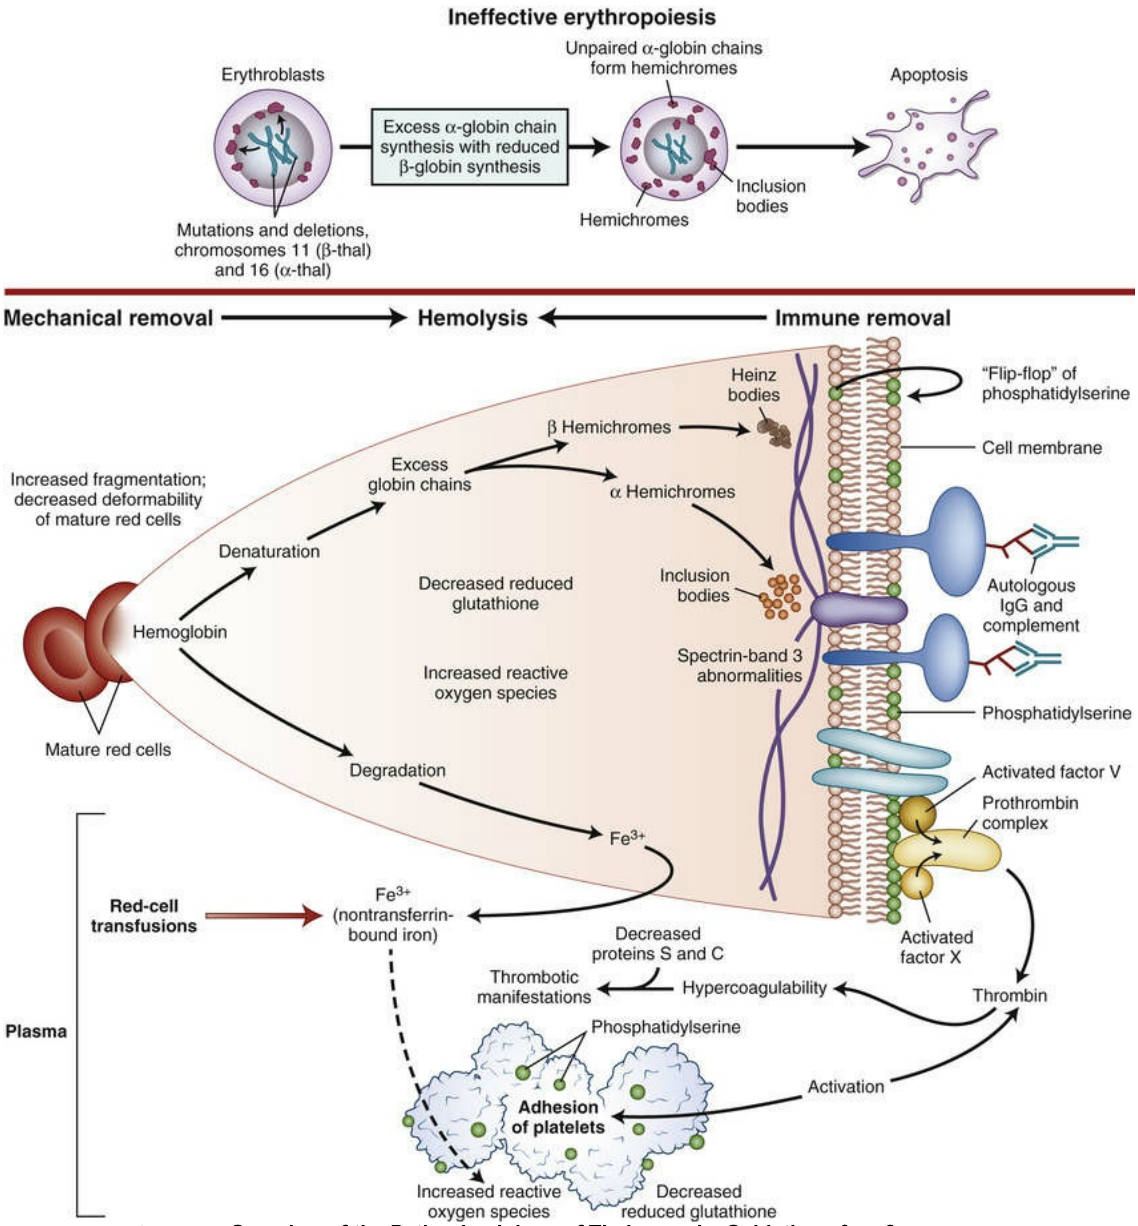
Hb, hemoglobin type; *nl*, normal; ↑, increased; −, negative; +, positive.

DNA testing is increasingly available and cost effective, though it remains problematic as no single assay or panel detects all abnormalities. With the increasing application of high throughput genome sequencing to clinical medicine, it will not be long before comprehensive sequence-based assays will be available.

Pathophysiology

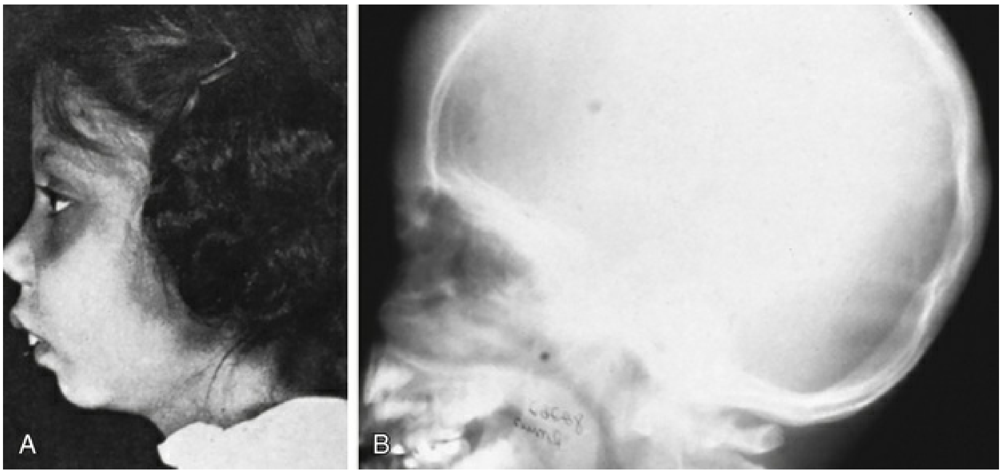
The pathophysiology of thalassemia is complex but in brief, unpaired globin chains lead to ineffective erythropoiesis and hemolysis, the degree of which depends on the specific form of thalassemia and the patient's genetic background (eFig. 90.16).[115] Free globin chains increase reactive oxygen species, whereas decreased glutathione and antioxidant stores result in oxidative damage to the fragile red cell membrane, as well as to apoptosis in a Fas-mediated process. The result is a cadre of processes contributing to the heterogeneity of disease presentation. Phosphatidyl serine moves to the outer leaf of the red cell membrane, enhancing macrophage-mediated destruction in the spleen and marrow and acting as a substrate for factors V and VIII binding, enhancing the generation of thrombin, which together with decreased protein C and S levels and increased platelet activation and adhesion leads to increased thrombosis. In an attempt to compensate for the hemolysis and ineffective erythropoiesis, medullary and extramedullary erythropoiesis lead to skeletal abnormalities such as the thalassemic facies (eFig. 90.17) and thinning of the cortex

of long bones, which, along with endocrine abnormalities (see the following section), lead to increased fractures. High levels of nontransferrin-bound iron from red cell destruction, increased intestinal absorption from inappropriately low levels of hepcidin, and transfusions lead to iron deposition, resulting in liver, cardiac, and endocrine dysfunction.



EFIG. 90.16 **Overview of the Pathophysiology of Thalassemia. Oxidation of α-, β-, or γ-hemoglobin subunits leads to the formation of hemichromes, whose rate of formation determines the rate of hemolysis. Because α-chains dissociate into monomers more readily than do β or γ chains, they form hemichromes at a faster rate, which explains why β-thalassemia is clinically much more severe than α-thalassemia. Precipitates of unpaired β-chains form single large inclusions known as Heinz bodies. This process occurs at a later stage of maturation than does the formation of smaller multiple inclusions because of the precipitation of unpaired α-chains. Hemichromes bind to or modify various components of the mature red-cell membrane, such as protein band 3, protein 4.1, ankyrin, and spectrin. After precipitation of hemichromes, heme disintegrates, and toxic non–transferrin-bound iron species are released. The resulting free iron catalyzes the formation of reactive oxygen species. Iron-dependent oxidation of membrane proteins and formation of red-cell "senescence" antigens such as phosphatidylserine cause thalassemic red cells to be rigid and deformed and to aggregate, resulting in premature cell removal. Phosphatidylserine is also**

involved in the activation of the coagulation system. (Used with permission from Rund D, Rachmilewitz E: Beta-thalassemia. N Engl J Med 2005;353:1135-1146. Copyright © 2005 Massachusetts Medical Society. All rights reserved.)



EFIG. 90.17 Facial and skull bone changes associated with thalassemia. (A) A child with ß-thalassemia with maxillary hyperplasia due to increased marrow activity. (B) A radiograph from the same patient demonstrating increased marrow activity in the skull. (From Zitelli BJ, Davis HW. Hematology and oncology. In: Atlas of Pediatric Physical Diagnosis. 5th ed. Elsevier; 2007. Copyright Elsevier 2007.)

Forms and Variations

α-Thalassemia

Typical laboratory findings are summarized in eFig. 90.18. Although alpha thalassemia leads to a tremendous burden on health worldwide and is well reviewed elsewhere, it is not a major cause of ICU admits in the United States, thus the focus will be on β-thalassemia major.[116]

Data extracted from Higgs DR, Bowden DK: Clinical and laboratory features of alpha-thalassemia syndromes. In Steinberg MH, Forget BG, Higgs DR, Nagel RL, editors: *Disorders of hemoglobin*, Cambridge, UK, 2001, Cambridge University Press, pp 431–469 and from Galanello R and Cao A: *Alpha-thalassemia genereviews at genetests: medical genetics information resource*, Seattle, 2008, University of Washington.

Table shows typical results; exceptions occur.
nl = normal
↑= increased
↓= decreased
N/A: not applicable

1. Pattern of α-globin genes. α and – are the presence of active and deleted genes, respectively. The two genes on one chromosome are separated from those on the other by a "/".
2. Hemoglobin level (Hgb)
3. Must use age specific values. MCV can be lowered by β-thalassemia trait.
4. Brilliant crescyl blue (BCB) or inclusion body prep. Results vary by lab, but this can be done semi-quantitatively. This assay is unreliable in the presence of other hemoglobins (e.g. HbS or HbE). This can be negative when both α- and β-thalassemia are present.
5. HbA_2 results vary depending on laboratory method.
6. Values are lower for a two gene deletion in cis (-- / αα), than in trans (-α / -α).

EFIG. 90.18 Red blood cell indices in adults with α-thalassemia.

β-Thalassemia

In contrast to α-thalassemia, the plethora of β-gene mutations leads to a continuous spectrum of disease. β0-thalassemia denotes nonexpressing alleles, whereas β+-thalassemia is used for genes that express a reduced amount of normal protein. Most mutations do not eliminate ε- or γ-gene expression, thus it is unusual for clinical complications to occur until several months of life, when infants become dependent on adult β-globin chains. Nomenclature is based on this continuum of phenotypic severity rather than genotype. β-thalassemia trait, also referred to as thalassemia minor, is due to a single silent allele and is benign and only of note for primary care and genetic counseling. The term *thalassemia major* (also known as Cooley anemia) is reserved for transfusion-dependent phenotypes, whereas those with clinical sequelae, but who are not dependent on transfusions for survival, are referred to as having thalassemia intermedia. The latter require the most clinical decision making as there is increasing awareness of the high morbidity in many of these patients, as many benefit from transfusion.[117]

HbE/β0-Thalassemia

Of the numerous hemoglobin variants, this compound heterozygous state is worth special mention. The HbE mutation is common throughout Southeast Asia and results in an RNA splicing abnormality and a destabilizing amino acid substitution, leading to a thalassemic allele. When combined with another β-thalassemic allele the phenotype is extraordinarily variable, with some thriving, and a subset being transfusion dependent.[118,119] Management is similar to that for other thalassemias and guided by clinical presentation, not genotype.

Natural History

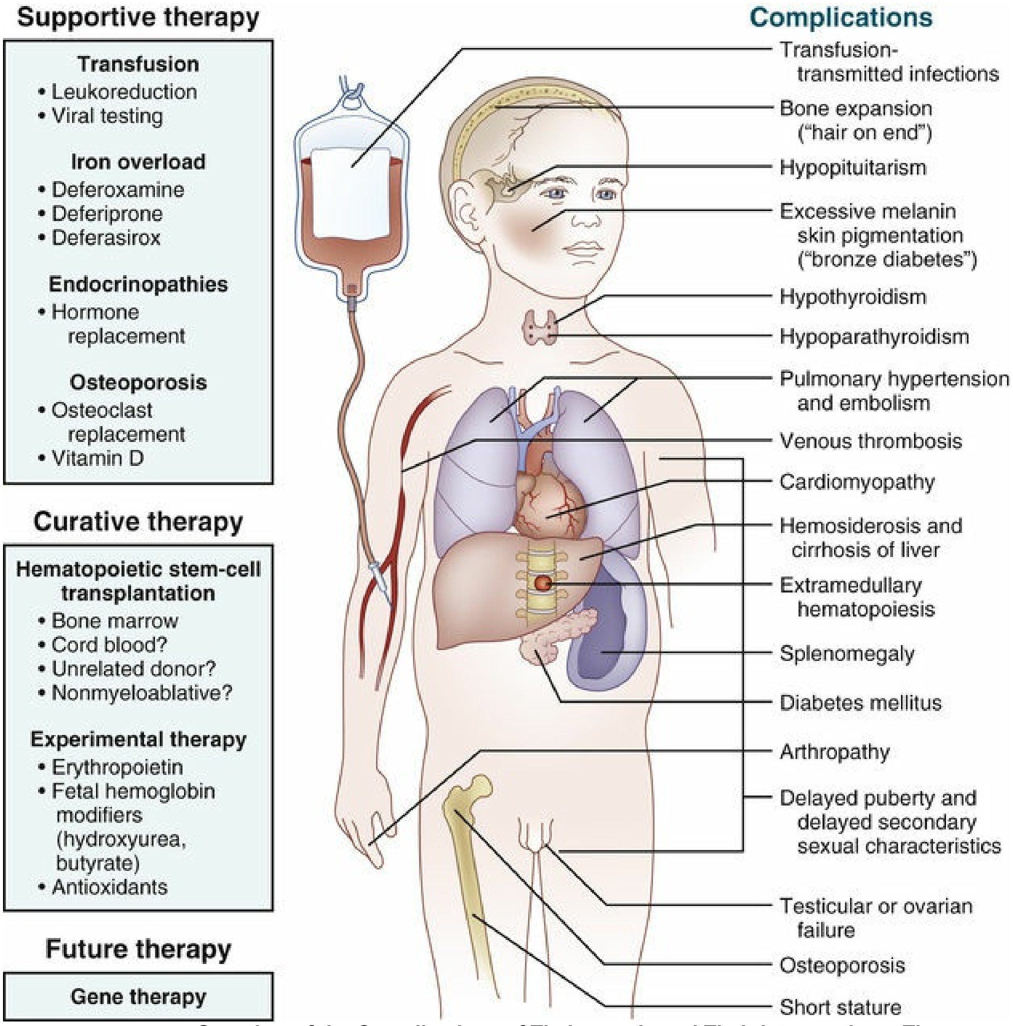
Natural history is highly variable depending on the genotype, modifying genetic factors, and, critically, if and at what interventions such as transfusion and chelation are available. If not diagnosed by newborn screening or from a known familial risk, children can present with anemia, growth delays, bony abnormalities, iron overload (even if untransfused), and, most common for the intensivist, congestive heart failure.

Assessment of Iron Overload

Direct tissue measurement of iron is essential. Though inexpensive, serum ferritin is a poor indicator of iron stores; it is elevated with inflammation and does not correlate well with tissue iron content, especially in chelated patients.[120,121] MRI-based assessment of iron overload is based on relaxation times correlating with iron content and is now widely accepted.[121,122] Techniques evolve rapidly, and standards and practices vary greatly, making it essential to discuss options with local radiologists. Ferriscan is a commercially available test where data are sent out for analysis, and it is limited to the assessment of hepatic iron.[123] In contrast, T2* imaging is increasingly available and allows simultaneous assessment of hepatic and cardiac iron and, potentially, other target organs.[121,124] A lower T2* correlates with higher degrees of iron overload (see “Cardiac Complications,” presented later).

Spectrum of Disease

Although a summary of clinical problems and management is listed here and in eFig. 90.19, the reader is referred to the Northern California Comprehensive Thalassemia Center standard of care guidelines[125] for more details (http://thalassemia.com/documents/SOCGuidelines2012.pdf).



EFIG. 90.19 Overview of the Complications of Thalassemia and Their Interventions. The anemia that is associated with thalassemia may be severe and is accompanied by ineffective erythropoiesis, with bone expansion and extramedullary hematopoiesis in the liver, spleen, and other sites, such as paravertebral masses. Transfusion therapy, which is the mainstay of treatment, allows for normal growth and development and suppresses ineffective erythropoiesis. Transfusion-transmitted infections (primarily hepatitis B and C) are an important cause of death in countries where proper testing is not available. Iron overload results both from transfusional hemosiderosis and excess gastrointestinal iron absorption. Iron deposition in the heart, liver, and multiple endocrine glands results in severe damage to these organs, with variable endocrine organ failure. The endocrinopathies can be treated with hormone replacement. However, the most serious result of iron overload is life-threatening cardiotoxicity, for which chelation therapy is required. Thalassemia can be cured by bone marrow transplantation. Experimental therapies to ameliorate the anemia that have been or are currently under investigation include fetal hemoglobin modifiers and antioxidants. In the future, gene therapy or other molecular methods may be feasible. (Used with permission from Rund D, Rachmilewitz E. Beta-thalassemia. N Engl J Med. 2005;353:1135-1146. Anemia

Although there is much debate as to the optimal Hgb that should be targeted, in the ICU one must factor in the acuteness of the anemia, the degree of cardiovascular compromise, and the patient's baseline Hgb. A baseline level of under 6 g/dL is often the threshold for initiating chronic transfusions, though a higher threshold is used if growth, skeletal malformations, or extramedullary erythropoiesis becomes problematic. The goal should be to maintain an Hgb of 9 to 10 g/dL pretransfusion (10 to 12 g/dL if cardiac disease is present) but no higher than 14 g/dL

posttransfusion. As with SCD, profound anemia or cardiac compromise may require a slow transfusion, diuretics, or even an exchange transfusion to avoid congestive heart failure. Blood products should be leuko-reduced to minimize alloimmunization, febrile nonhemolytic transfusion reactions, and CMV transmission. As with SCD, blood should be matched for ABO, Rh (Cc, D, Ee), and Kell. Family and related donor transfusion should be avoided if a hematopoietic stem cell transplant is to be considered, as alloimmunization to donor antigens increases graft rejection.

Transfusion-Related Complications

Chronic or frequent transfusions increase iron overload, the risk of alloimmunization, and infectious risk[126] (also described in Chapter 94). Because of inappropriately low hepcidin levels, the ability of the body to absorb iron is unopposed, leaving blood loss and sloughing of endothelial and skin cells as the only mechanism to decrease iron in the face of iron overload. This is estimated to lead to a loss of 1 mg/day in an adult, which pales in comparison to the approximately 200 mg of iron in each unit of blood. Although previous focus was on hepatic iron overload and cirrhosis, there is increasing awareness of iron overload in the heart, pituitary, and endocrine organs leading to dysfunction (see the following section) and excessive melanin production leading to bronze pigmentation. Iron overload requires chelation; a summary of chelation drugs and potential toxicities can be found in eFig. 90.20.

IRON CHELATOR PROPERTIES

Agent	Route	Half-life of drug (hours)	Schedule	Clearance	Side effects and toxicity
Deferoxamine (Desferal)	Slow infusion: intravenous or subcutaneous	0.5	Eight to 24 hours per day, 5 to 7 days per week	Renal, hepatic	Dermatological, ocular, auditory
Deferasirox (Exjade)	Oral	12 to 16	Once daily	Hepatobiliary	Gastrointestinal, renal, hepatic
Deferiprone (L1)	Oral	2 to 3	Three times per day	Renal, cardiac	Hematological (neutropenia, agranulocytosis), arthropathic

EFIG. 90.20 Iron chelator properties.

Cardiac Complications

Cardiac failure due to iron overload, defined as a low ejection fraction with a component of cardiomyopathy, is the major cause of ICU admission and death in thalassemic patients.[127,128] A thalassemic patient in failure should be assumed to have cardiac iron overload until proved otherwise.[125] Risk factors include transfusion

history and underchelation. Untreated overload can also lead to dysrhythmias including atrial fibrillation and ventricular tachycardia, as well as conduction disturbances and heart block.[127,128] Excess unbound iron from transfusion and inappropriate gastrointestinal absorption freely penetrates cardiac myocytes leading to progressive tissue damage. Iron accumulates predominantly in the epicardial portion of the ventricular septum and ventricular free walls, stimulating the production of free radicals and resulting in peroxidative tissue damage, decreased cardiac contractility, and dysrhythmias. This, in combination with the high output state from chronic anemia, results in the early development of cardiac failure. Cardiac iron overload occurs well after the liver becomes overloaded. Initial cardiac iron deposition increases the influx of additional iron resulting in a rapid accumulation and the potential for rapid decline, a wide range of dysrhythmias, and failure after years of normal function. The clinical presentation is that of congestive heart failure; however, some present solely with abdominal pain due to liver distenion. Clinicians should maintain a low threshold to evaluate for cardiac dysfunction. With advances in both transfusion and chelation therapy, survival is increasing but is highly dependent on the underlying thalassemia as well as access to transfusion and chelation.

Assessments

Cardiac iron accumulation and function must both be assessed. Ferritin and assessments of liver iron concentration (LIC) cannot be used to assess cardiac risk because kinetics of iron deposition and unloading differ between the organs. Iron assessment by T2* is invaluable as one can assess cardiac iron, as well as LIC.[124] A T2* of over 20 ms is not associated with increased cardiac risk. In contrast, a value of 10 to 20 ms denotes overload and increased cardiac risk, and a T2* of under 10 ms portends a high risk of cardiac dysfunction and an emergent situation requiring aggressive chelation (eFig. 90.21).[120,125,127-129] Echocardiography is essential, and left ventricular dysfunction is highly suggestive of iron overload.[130] Given the high output state, some suggest the cutoff for a normal ejection fraction in thalassemics should be 60%.[131] Electrocardiogram often revels biventricular dysfunction with left ventricular hypertrophy, a prolonged PR interval, bradycardia, ST-T wave change, and T-wave inversions. Iron-related parathyroid and thyroid and adrenal dysfunction, as well as vitamin D and thiamine status, should be investigated, as they may impact cardiac function.

GUIDELINES FOR IRON CHELATION THERAPY AND MONITORING IN THALASSEMIA

Liver iron concentration (LIC)	Ferritin	Recommended chelation	Monitoring	Comments
<3,000 µg/g	<1,000 ng/mL	Lower the dose at < 1,000 ng/mL and hold medication at < 500 ng/mL	Monitor ferritin monthly; start reduced-dose chelation when ferritin goes up to 500 ng/mL and full dose at 1,000 ng/mL, depending on age and risk factors	
3,000 to 7,000 µg/g	1,000 to 2,500 ng/mL	Maintain existing therapy	Monitor ferritin every 3 months	Note changes in trends. More aggressive therapy may be indicated, depending on organ dysfunction.
>7,000 µg/g	>2,500 ng/mL	Intensive chelation	Monitor ferritin every 2 to 3 months, and check LIC within 6 months	Note changes in trends. More aggressive therapy may be indicated, depending on organ dysfunction.
Excess cardiac iron without cardiac dysfunction; T2* < 20 ms		Intensive chelation	Monitor ferritin every 2 to 3 months, and check LIC within 6 months	Intensive chelation consists of at least 12 hours of deferoxamine per day, 7 days per week, or maximum tolerated deferasirox, as well as consideration of combination therapy.
Iron-induced cardiomyopathy, T2* <20 ms; or T2* <10 ms without cardiomyopathy		Maximum chelation: 24-hour deferoxamine therapy in combination with deferiprone (alternatively, in combination with deferasirox-limited combination data available)	Monitor ferritin every 2 to 3 months, and check LIC within 6 months; monitor cardiac function within 6 months. Monitor intensively with cardiology consultation and iron chelation specialist.	Intensive chelation consists of at least 12 hours of deferoxamine per day, 7 days per week. Combination therapy with deferiprone or maximum tolerated deferasirox is recommended.

Notes: Ferritin may be a misleading measurement; liver iron is the much more accurate one. Young children may have more toxicity with chelators and may need dose adjustment.

Therapeutic index (TI) is often used in determining the deferoxamine dose when ferritin is analyzed. The therapeutic index is equal to the mean daily dose (mg/kg) / serum ferritin (mg/l). The target is to maintain the value of TI at under 0.025. The mean daily dose of deferoxamine is calculated by multiplying the dose administered in each treatment by the total number of doses administered per week, then dividing by seven—the number of days in a week. Ferritin measurements should be accompanied by periodic LIC measurements.

Consultation with specialists in iron overload should be considered in dose adjustments.

Non-transfused or intermittently transfused patients should receive chelation therapy and have their iron stores closely monitored. Their dosing should be modified on an individual basis with consultation.

LIC refers to dry weight, which is the standard method for reporting liver iron by liver biopsy and MRI. The wet weight conversion, which is a direct measurement determined by SQUID, is achieved using a divisor of 5 to 6.

EFIG. 90.21 Guidelines for iron chelation therapy and monitoring in thalassemia.

Management

The key to management of iron-related cardiac dysfunction is chelation. For details see the Standards for Care Guidelines for Thalassemia and eFig. 90.21 in the appendix.[125] High-risk cardiac patients (failure, arrhythmias, a cardiac T2* <10 ms, or an LIC >30 μg/g dry weight) demand emergent intervention with deferoxamine at higher dosing than for routine chelation. Optimal chelation strategies in emergent situations are evolving rapidly, thus an expert on chelation should be consulted. Conservative therapy consists of 24-hour continuous deferoxamine infusion at 50 to 100 mg/kg/day, 7 days a week, given intravenously or subcutaneously depending on access and comfort.[125] Deferoxamine can lead to histamine-mediated hypotension when given intravenously, so blood pressure should be monitored closely. After the initiation of continuous deferoxamine, deferiprone or deferasirox should be considered as addition of either can be beneficial.[132] Arrhythmias often resolve promptly with chelation and are commonly treated with amiodarone. Due to the diffuse injury and reversibility with chelation, ablation is not recommended. Although ascorbic acid releases iron, facilitating chelation, it should not be used initially as the increased release of iron may lead to cardiac damage. Total iron must be assessed to avoid toxicity from overchelation. Afterload reduction, diuresis, and inotropic support should be considered, and serial echoes to follow shortening and ejection fractions are indicated. Additional measures to optimize cardiac function include maintaining a pretransfusion Hgb of 12 g/dL, protecting oxidative damage with carnitine, correcting thyroid and parathyroid deficiencies, and administering intravenous calcium with oral vitamin D to maintain cardiac contractility. Unless emergent, interventions such as pacemakers and cardiac transplant should not be considered until after cardiac iron has been reduced because dysfunction is often reversible with chelation.

Hepatic Dysfunction

The intensivist should remain aware that liver damage and dysfunction from iron overload, transfusion-related viral hepatitis, medications, autoimmune disease, and genetic factors such as α1-antitrypsin deficiency and Wilson disease are common in thalassemia. Assessment of liver damage is often multimodal, requiring a T2* for LIC, and CT or routine MRI to assess tissue damage and cirrhosis. Liver biopsy may be necessary to more fully assess the underlying damage.

Thrombosis and Pulmonary Emboli

Thrombotic complications of pulmonary emboli, arterial occlusion, portal thrombosis, deep vein thrombosis, and stroke are increased in thalassemia, especially after splenectomy. Enhanced thrombin generation due to factor V and VIII alterations as well as decreased protein C and S levels and increased platelet aggregation lead to a thrombotic state resulting in increased venous thrombosis and emboli (see eFig. 90.16).

Pulmonary Hypertension

Although pulmonary hypertension is common in thalassemia, the true prevalence is not known. As with SCD (discussed previously), NO destruction secondary to free hemoglobin from hemolysis contributes to pulmonary hypertension, as do the direct

effects of iron overload on the vascular endothelium and myocardium stiffness and function. In addition, cell fragments or debris can cause vasoconstriction in the pulmonary vasculature, which is worsened with splenectomy. As in SCD, screening by transthoracic echo is common, with concerns raised for a TR jet of over 2.5 m/sec and a diagnostic catheterization if over 3 m/sec.[125,133,134] Treatment should address the various pathways contributing to pulmonary hypertension.[125,133] Maintaining the Hgb over 9.5 g/dL helps suppress ineffective erythropoiesis and the resultant hemolysis and NO destruction and decrease cell debris. If evidence of cardiac dysfunction from iron overload chelation is critical, oxygenation should be maintained, keeping saturations over 95%, and anticoagulation should be considered. For persistent disease, sildenafil should be considered, though there are some data for the use of bosentan and epoprostenol.[125,133]

Therapies and Interventions

Interventions for specific complications are described previously, in the Northern California Comprehensive Thalassemia Center standard of care guidelines,[125] and in eFig. 90.19. Although transfusions are the mainstay of therapy for severe thalassemia, guidelines for when to initiate transfusions and what Hgb to target vary with each individual's presentation and among centers. In the acute setting it is essential to remain aware of the patient's recent baseline Hgb, maintain a higher Hgb (10 to 12 g/dL) for cardiac failure, and consult with the hematologist. Although HSCT and gene therapy are potentially curative and inducers of nonadult globin genes are actively being optimized, none are currently useful in the acute ICU setting.

Hematopoietic Stem Cell Transplantation

Currently hematopoietic stem cell transplantation (HSCT) is the most available cure for thalassemic patients, though a handful have been cured by gene therapy. For HSCT, long transfusion histories increase the chance of graft failure, necessitating an aggressive myeloablative conditioning regimen, which in turn can lead to a high treatment-related toxicity, especially if significant end-organ damage is present. Thus success depends on having an adequate donor and the degree of end-organ damage. The latter is assessed using the Lucarelli staging system that factors in the degree of hepatomegaly, the degree of portal fibrosis, and the quality of the chelation treatment given before the transplant.[135,136] With improved pretransplant care and increased myeloablation and immunosuppression, even the highest risk groups have done well with matched-sibling donors with 90% event-free survival, 96% overall survival, and 7% rejection rates.[136-139]

Gene Therapy

Gene therapy addresses three major barriers to HSCT: graft failure from rejection, the difficulty of finding a suitable donor, and graft-versus-host disease. Though many novel strategies are being evaluated, the open clinical trials use viral vectors containing β-like globin genes to infect a patient's CD34+ hematopoietic progenitors, followed by autologous transplantation. Several patients have become transfusion independent.[140,141] Although numerous approaches are being investigated, most excitingly the technology to perform genome editing to correct thalassemic and SCD

mutations is rapidly improving.

Inducers of Other β-Like Genes

Induction of HbF remains the holy grail of β-thalassemia and SCD therapy. After decades of limited success, understanding the multiple pathways involved in globin gene regulation is facilitating the development of multiple classes of novel regulators of HbF.[112-114] Additional approaches are reviewed elsewhere.[110]

CHAPTER 91

Coagulation and Coagulopathy in Critical Illness

Robert I. Parker

PEARLS

- Hemostasis is a dynamic process; once bleeding occurs, clot formation and degradation (fibrinolysis) are also initiated.
- Coagulation is an integral part of inflammation and will often lead to microvascular thrombosis.
- A consumptive coagulopathy should always be considered in a patient with diffuse or generalized bleeding; however, liver disease and vitamin K deficiency are much more common.
- The international normalized ratio is not an appropriate surrogate for the prothrombin time in patients not on vitamin K antagonist anticoagulation, and a prolonged prothrombin time in the presence of liver disease is not an accurate predictor of bleeding risk.
- Localized bleeding in a trauma or postoperative patient is generally the result of an anatomic lesion rather than a systemic coagulopathy.
- Thrombotic events are being recognized with increased frequency in the pediatric intensive care unit; no more than 60% of children with documented thromboses will be found to have an identifiable underlying hematologic abnormality.
- The presence of a central venous catheter is the most common identified thrombotic risk factor in critically ill children.
- rhF.VIIa is effective in controlling bleeding unresponsive to other measures, but its use has not yet been shown to improve outcome.
- The absence of a prolonged prothrombin time or activated partial thromboplastin time does not rule out the possibility of an abnormality in hemostasis.
- Clot formation in vivo is critically dependent on factor VII and tissue factor.

Introduction

Abnormalities in hemostasis often accompany critical illnesses whether as an intrinsic component of the illness (eg, sepsis, trauma) or merely a byproduct or a comorbidity not directly related to the critical illness that resulted in pediatric intensive care unit (PICU) admission. Although many of the abnormalities noted in critical illness may lead to excessive bleeding, not all hemostatic alterations produce the same result. In some, the bleeding may be severe and systemic or relatively mild; in others the imbalance in hemostasis may favor excessive clot formation. In some conditions the abnormality may in fact represent a laboratory artifact that is without clinical manifestations (Table 91.1). For the practicing intensivist to adequately and accurately assess the patient with a potential or clinically apparent hemostatic defect, it is necessary to briefly review the initiation and regulation of hemostasis and how it is measured in the clinical lab.

TABLE 91.1

Overview of Coagulation Disorders Seen in the Intensive Care Unit

Conditions Associated With Serious Bleeding or a High Probability of Bleeding
Disseminated intravascular coagulation
Liver disease/hepatic insufficiency
Vitamin K deficiency/depletion
Massive transfusion syndrome
Anticoagulant overdose (heparin, warfarin)
Thrombocytopenia (drug induced, immunologic)
Acquired platelet defects (drug induced, uremia)
Thrombotic Clinical Syndromes (see Chapter 92)
Thrombotic thrombocytopenia purpura/hemolytic uremic syndrome
Deep venous thrombosis
Pulmonary embolism
Coronary thrombosis/acute myocardial infarction
Laboratory Abnormalities Not Associated With Clinical Bleeding
Lupus anticoagulant
Reactive hyperfibrinogenemia
Other Selected Clinical Syndromes
Hemophilia (A and B)
Specific factor deficiencies associated with specific diseases
Amyloidosis–factor X, Gaucher disease–factor IX, nephritic syndrome–factor IX, antithrombin III
Cyanotic congenital heart disease (polycythemia, qualitative platelet defect)
Depressed clotting factor levels (newborns)

Overview of Hemostasis

Hemostasis and coagulation are not synonymous. Although coagulation is the process by which blood transforms from a liquid to a solid state (ie, the process of clot formation), hemostasis includes all of the processes in the arrest of bleeding. Additionally, the working definition of hemostasis often includes the restoration of blood to its liquid state through the process of fibrinolysis. Traditionally, coagulation has been presented as a set of discrete units, the “intrinsic,” “extrinsic,” and “common” pathways, that progress in an orderly non-overlapping sequence (Fig. 91.1). This depiction is useful when explaining the various tests employed to assess clot formation (eg, prothrombin time [PT], activated partial thromboplastin time [aPTT], thrombin time [TT]). However, this representation of coagulation does not include any involvement of inflammatory mediators, platelets, endothelial cells,

adhesive glycoproteins, or thrombolytic factors in the process of hemostasis.

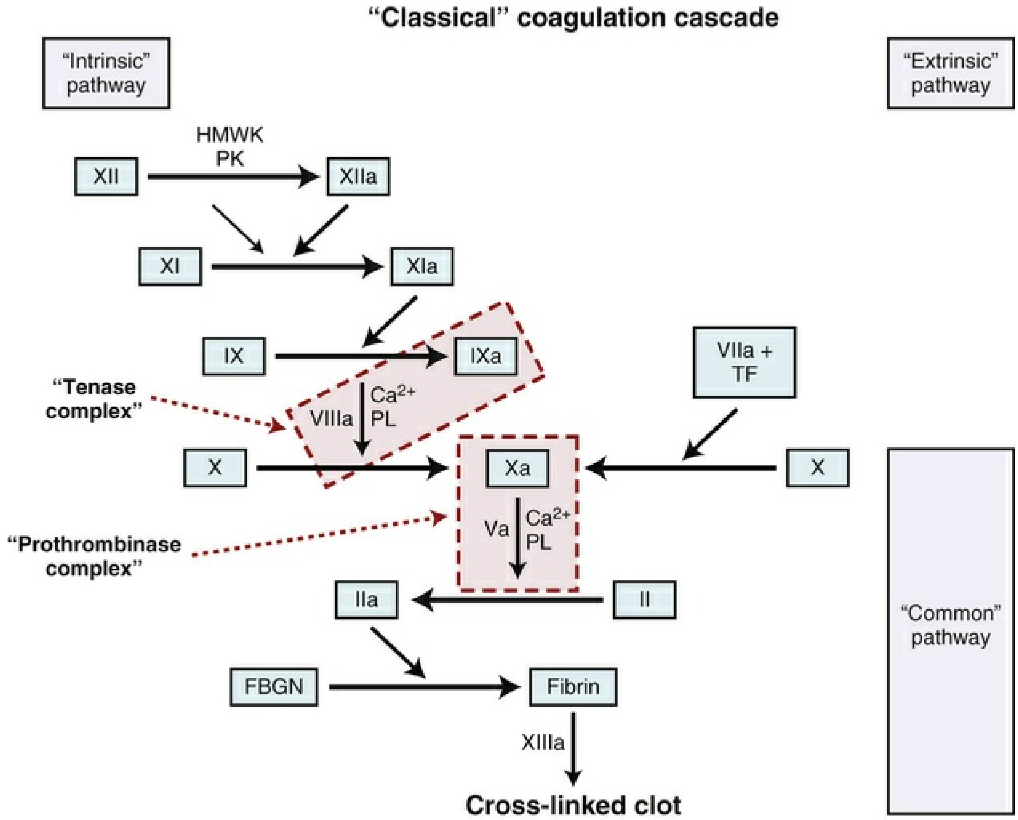

FIG. 91.1 Coagulation is initiated either through the "intrinsic" pathway by activation of factor XII in the presence of high-molecular-weight kininogen (HMWK) and prekallikrein (PK) or through activation of the "extrinsic" pathway by tissue factor. Roman numerals indicate zymogen clotting factors; "a" indicates activated forms of the clotting factors. (Factor II is prothrombin and F.IIa is thrombin); *FBGN*, fibrinogen

Historically, the "intrinsic" pathway, beginning with the activation of factor XII (F.XII) to activated factor XII (F.XIIa) in contact with some biological or foreign surface, was believed to be physiologically the most important in the initiation of clot formation because deficiencies of either factor VIII (F.VIII) (hemophilia A) or F.IX (hemophilia B) produced a severe bleeding diathesis. However, we now understand that the activation of F.X to F.Xa through the action of the F.VIIa/tissue factor (TF) complex plays a more central role in this process.[1,2] The elements of the clotting cascade act in concert, hence the use of the term *tenase* to describe the action of F.VIIa/TF complex, along with the F.IXa/F.VIIIa complex on the activation of F.X to F.Xa, and the use of the term *prothrombinase* to describe the F.Xa/F.Va complex, which cleaves prothrombin (F.II) to form thrombin (F.IIa). In addition, several points of "crosstalk" exist between the two arms of the clotting cascade, with F.VIIa being able to enhance the activation of F.IX (to F.IXa) and F.XI (to F.XIa), further highlighting the central role of F.VIIa and TF in vivo (Fig. 91.2). Furthermore, various "positive feedback" loops involving thrombin enhance the "upstream" activation of the clotting process. The activation of coagulation is initiated from TF, which is found in the subendothelial matrix, on cellular elements (eg, monocytes)

and circulating freely in plasma as soluble TF. However, clotting does not occur in free-flowing blood but rather on surfaces. Platelets, endothelial cells, the subendothelial matrix, and biological polymers (catheters, grafts, stents, etc.) provide these surfaces for clot formation, and each plays a critical role in clot formation.

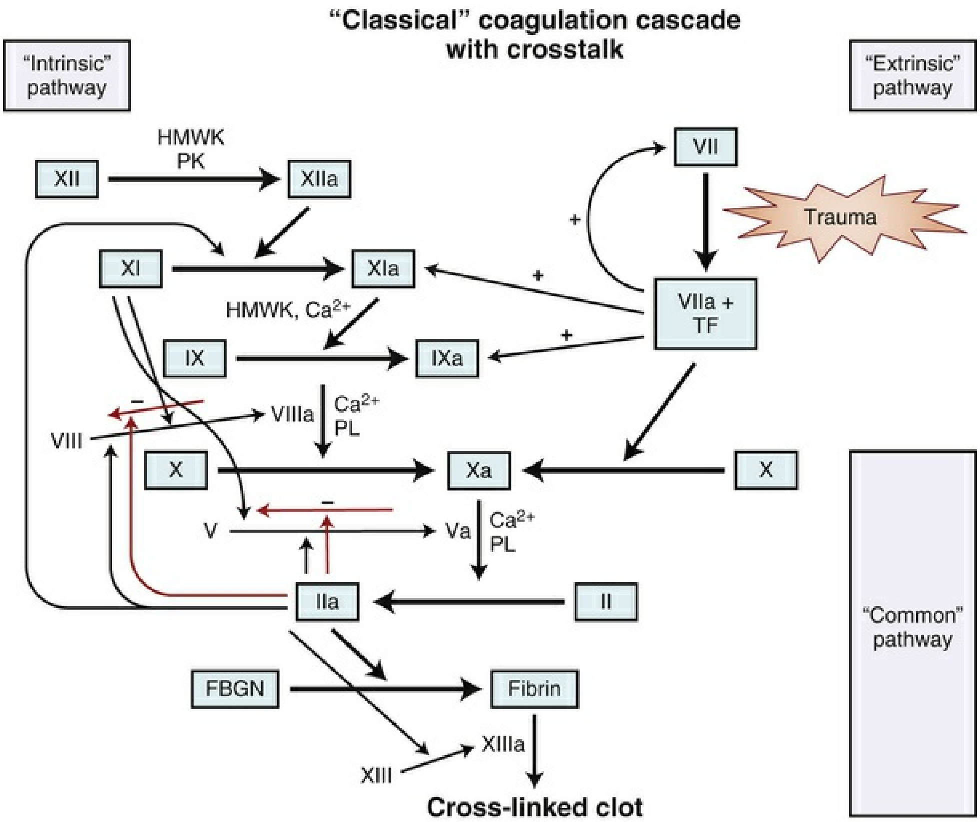

FIG. 91.2 Modified clotting cascade indicating crosstalk between the intrinsic and extrinsic pathways by the action of factor VIIa/tissue factor (TF) enhancing the conversion of factor XI to activated factor XI (XIa) and factor IX to IXa. *HK*, high-molecular-weight kininogen; *PK*, prekallikrein; *PL*, phospholipid.

Platelets not only initiate the clot formation through the formation of a platelet plug, but more important, they provide specific proteins that regulate the clotting response (F.VIII, inhibitors of fibrinolysis, etc.) to the area of bleeding and provide a surface on which co-localization of clotting factors occurs for efficient clot formation (Fig. 91.3). Under "normal" (ie, resting, unstimulated) conditions, platelets do not adhere to the vascular endothelium, but upon stimulation or when the endothelium is mechanically disrupted (eg, cut) or activated by inflammation, platelets will adhere to the endothelial cell or subendothelial matrix via a von Willebrand factor-dependent mechanism. Once adherent, activated platelets secrete various molecules that further enhance platelet adherence and aggregation, vascular contraction, clot formation, and wound healing.[3]

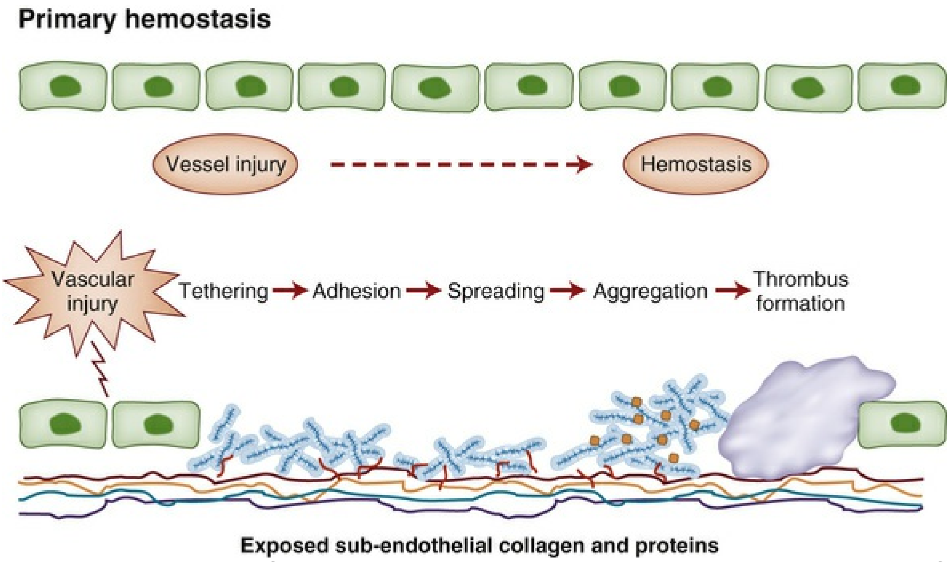

FIG. 91.3 The role of platelets in mediating primary hemostasis at sites of vascular injury. Platelets are initially activated and express specific adhesion receptors on their surface, followed by adhesion to activated endothelial cells and exposed subendothelial components (eg, collagen, von Willebrand factor). Subsequent platelet aggregation occurs with the development of a primary platelet plug. Coagulation occurs on the developing platelet plug with the creation of a fibrin clot.

The endothelium is a specialized organ that is integral to the regulation of hemostasis; it presents a nonthrombogenic surface to flowing blood and enhances clot formation when the endothelium is disrupted by trauma or injured by infection or inflammation[4,5] (see also Chapter 27). This process involves multiple components of the protein C pathway (Fig. 91.4). The normal endothelium produces inhibitors of blood coagulation and platelet activation and modulates vascular tone and permeability. Endothelial cells also synthesize and secrete components of the subendothelial extracellular matrix, including adhesive glycoproteins, collagen, fibronectin, and von Willebrand factor. When this system is disrupted, bleeding occurs. However, when injured, the endothelium often becomes a prothrombotic rather than an antithrombotic organ, and unwanted clot formation may occur.

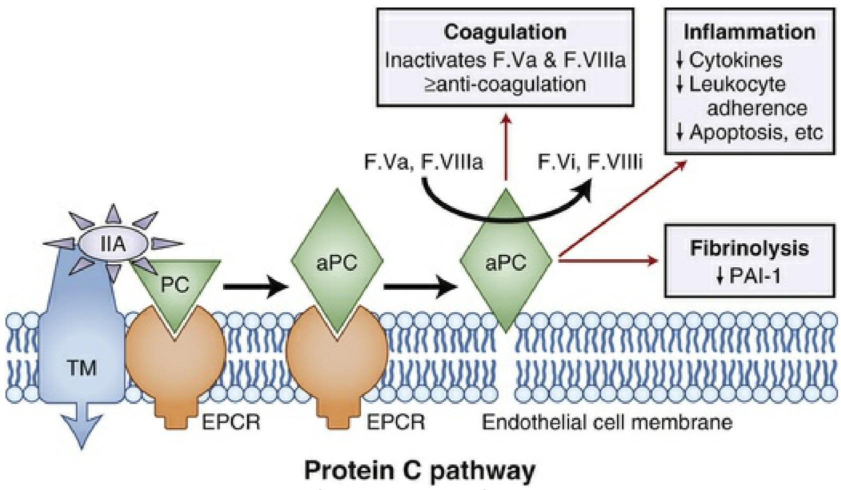

FIG. 91.4 The interaction of the protein C system with the endothelium:

thrombin bound to thrombomodulin (TM) modifies protein C bound to the endothelial protein C receptor on the cell surface to generate activated protein C (APC). APC acts as a natural anticoagulant by inactivating activated factors V (F.Va) and VIII (F.VIIIa), modulating inflammation by down-regulating the synthesis of proinflammatory cytokines, leukocyte adherence, and apoptosis and enhancing fibrinolysis by inhibiting thrombin-activatable fibrinolysis inhibitor (TAFI) and plasminogen activator inhibitor type 1 (PAI-1). *C4Bbp*, C4b binding protein; *+PS*, in the presence of protein S; *sTM*, soluble thrombomodulin; *sEPCR*, soluble endothelial cell protein C receptor.

Interaction of Coagulation and Inflammation

Coagulation has been identified as an integral part of the immune response, and evidence exists that this system developed during evolution as an intrinsic component of human host defense. The importance of this link between inflammation and coagulation is supported by the recognition that disseminated intravascular coagulation (DIC), when accompanied by sepsis and a systemic inflammatory response, results in a more severe clinical picture, higher degree of organ dysfunction, and a higher mortality. In DIC, coagulation pathways are activated, natural inhibitory pathways are dysfunctional, and the fibrinolytic system is dysregulated—all direct or indirect consequences of an inflammatory response. The natural inhibitory pathways of coagulation are of particular interest in this intersection of coagulation and inflammation, as potential therapies have been based around these systems.[6,7] Coagulation may be initiated in the flowing blood, on the endothelial surface, at endothelial lesions, in the perivascular tissues, and in areas not directly linked to the vascular bed, and it may or may not be associated with the formation of fibrin clots.[6]

During sepsis, TF expression is up-regulated in activated monocytes and endothelial cells as a response to endotoxin and other pathogen-associated/pathogen-initiated events, with the consequence being the secretion of proinflammatory cytokines and activation of coagulation leading to increased thrombin generation. Prior to its neutralization by antithrombin, thrombin plays a central role in coagulation and inflammation through the induction of procoagulant, anticoagulant, inflammatory, and mitogenic responses.[8] Thrombin results in the activation, aggregation, and lysis of leukocytes and platelets, in increased expression of endothelial adhesion molecules, and in the secretion of proinflammatory cytokines (IL-6) (Fig. 91.5). Thrombin increases endothelial permeability by causing contraction of endothelial cells; it also stimulates cellular proliferation. The net result of thrombin generation is production of a procoagulant state; it leads to the formation of fibrin; activates coagulation factors V, VIII, IX, XI; and leads to the expression of TF and von Willebrand factor and the aggregation of platelets. However, thrombin also has antiinflammatory effects through the production of activated protein C (APC)[8] (see Fig. 91.4). Concurrent with coagulation activation, two other crucial mechanisms occur during sepsis. One is the depression of natural anticoagulant systems, involving antithrombin and protein C (PC), and the second is the inhibition of fibrinolysis through the production of plasminogen activator inhibitor type 1 (PAI-1) and thrombin-activatable fibrinolysis inhibitor (TAFI) (Figs. 91.4, 91.5, 91.6, and 91.7).

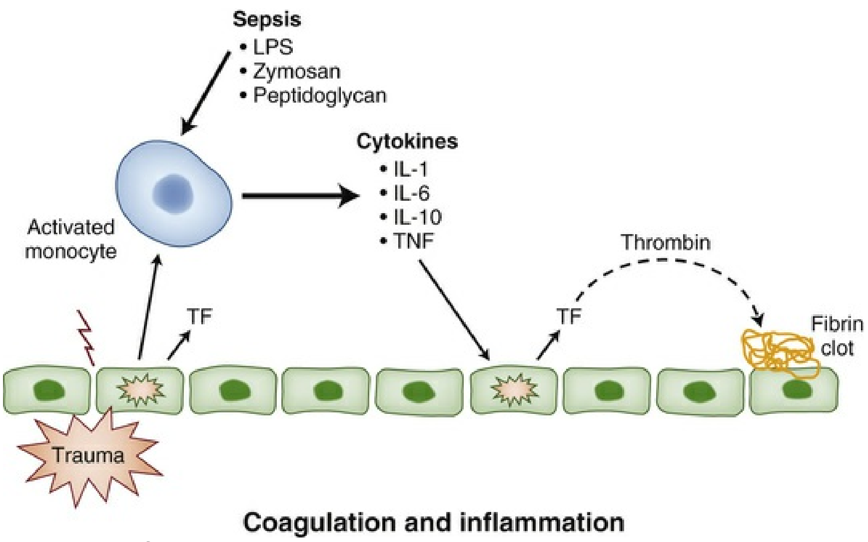

FIG. 91.5 Inflammation enhances coagulation through the induction of proinflammatory cytokines that induce tissue factor formation, which in turn decreases activated protein C (APC) formation, leading to enhanced thrombin and fibrin generation. In addition, the decrease in APC allows for greater inhibition of fibrinolysis through the action of plasminogen activator inhibitor type 1 (PAI-1).

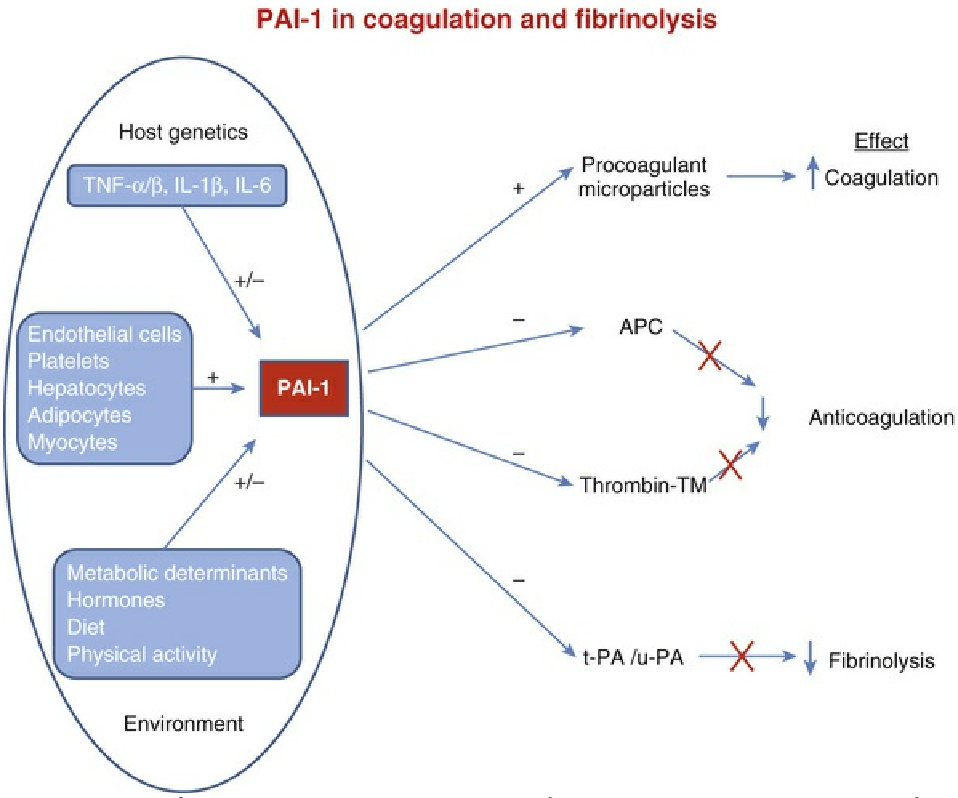

FIG. 91.6 Genetic and environmental influences on the expression of plasminogen activator inhibitor type 1 (PAI-1) and the importance of PAI-1 in the coagulation and fibrinolysis pathways. *TNF-α,* tumor necrosis factor-α; *APC,* activated protein C; *TM,* thrombomodulin; *t-PA,* tissue-type plasminogen activator; *u-PA,* urokinase-type plasminogen activator. (Modified from Hermans PW, Hazelzet JA. Plasminogen activator inhibitor type 1 gene

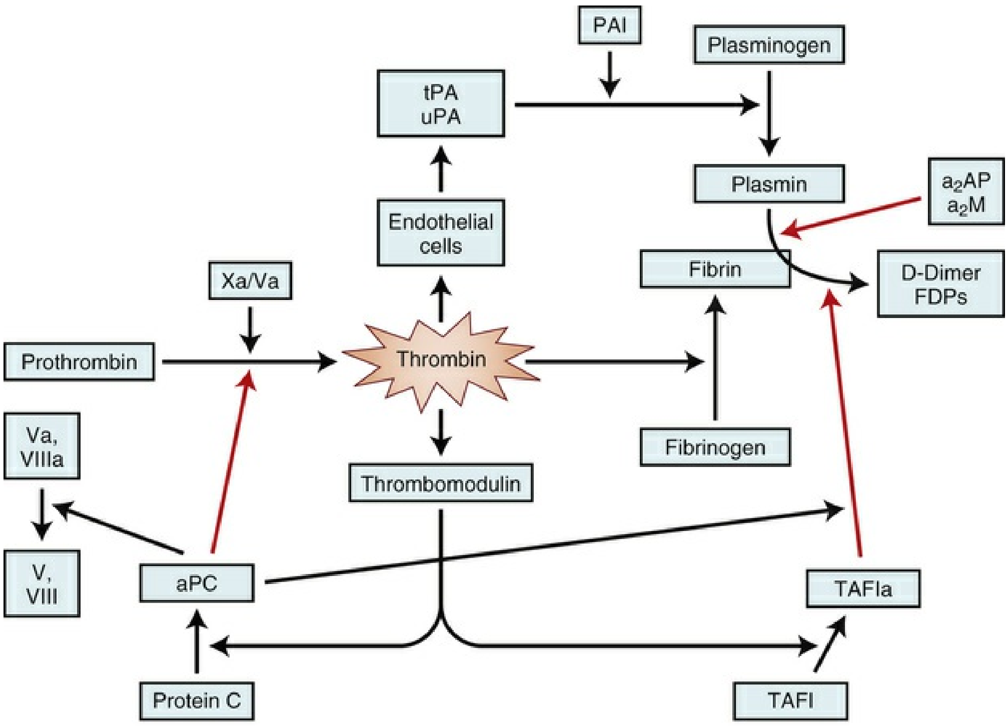
polymorphism and sepsis. Clin Infect Dis. 2005; 41[suppl 7]:S453-458, with permission.)



Fibrinolysis

FIG. 91.7 Fibrinolysis is initiated by the thrombin-mediated generation of uPA and tPA from endothelial cells and monocytes with subsequent generation of plasmin from plasminogen. The process is down-regulated by PAI-1 (plasminogen activator inhibitor type 1), a2AP (alpha-2-antiplasmin), and a2M (alpha-2-micorglobulin) and activated TAFI. *TAFIa*, thrombin-activatable fibrinolysis inhibitor; red arrows = inhibitory pathways.

Reduced levels of antithrombin III and PC may also occur in critically ill children as a result of decreased production secondary to impaired liver function, loss from the vascular space in the case of capillary leakage and consumption (eg, the conversion of PC to APC). However, antithrombin-III and PC levels are normally decreased at birth and do not achieve “near-adult” levels until 3 to 6 months of age; this fact must be taken into consideration when interpreting levels of these proteins in young infants.

Components of the PC system have been shown to be major regulators of coagulation (ie, natural anticoagulants) with decreased activity of this pathway resulting in pathologic thrombosis, and they have been shown to possess intrinsic immunomodulating properties (see Fig. 91.4). In vitro, APC inhibits tumor necrosis factor-α elaboration from monocytes, blocks leukocyte adhesion to selectins, and influences apoptosis.[8] The PC pathway is engaged when thrombin binds to thrombomodulin on the surface of the endothelial cells. In vivo, binding of PC to the endothelial cell PC receptor (EPCR) augments PC activation by the thrombin-thrombomodulin complex more than 10-fold. This receptor is shed from endothelial cells upon exposure to inflammatory mediators and thrombin, thereby down-

regulating PC activation in sepsis and inflammation. Additionally, it may also translocate from the plasma membrane to the nucleus, where it redirects gene expression. During translocation it can carry APC to the nucleus, possibly accounting for the ability of APC to modulate inflammatory mediator responses in the endothelium.[8]

The third important property of APC is its influence on fibrinolysis. APC is capable of neutralizing the fibrinolysis inhibitors PAI-1 and TAFI. PAI-1 is a 50-kDa glycoprotein of the serine protease inhibitor family. Its primary role in vivo is the inhibition of both tissue- and urokinase-type plasminogen activators. PAI-1 is an acute-phase protein that increases during acute inflammation. In patients with sepsis, increased levels of PAI-1 are associated with increased levels of various cytokines and acute-phase proteins, abnormal coagulation parameters, increased severity of disease, and poorer outcomes. The regulation of the production of PAI-1 is multifactorial (see Fig. 91.6). The 4G/5G insertion/deletion promoter polymorphism of the PAI-1 gene has been shown to affect PAI-1 plasma levels; individuals with the 4G/4G genotype display the highest PAI-1 levels, whereas those with the 5G/5G genotype display the lowest (the 4G/5G genotype results in intermediate levels). Differences in PAI-1 levels have been demonstrated to affect the risk of developing severe complications and death from sepsis, higher PAI-1 levels generally being associated with increased mortality in animal models of sepsis and higher severity of illness and organ dysfunction scores in septic patients, including children with meningococcal sepsis.[9-11] However, the regulation of PAI-1 levels is complex involving not only promoters of synthesis. Activated protein C can stimulate fibrinolysis by forming a tight 1 : 1 complex with PAI-1, leading to inactivation of this fibrinolysis inhibitor. High levels of thrombin lead to increased levels of activated protein C, which can complex to PAI-1. This complex is subsequently cleared from the circulation, resulting in PC depletion.[10]

Thrombin generation also increases the levels of TAFI, also known as carboxypeptidase R. TAFI is an important negative regulator of the fibrinolytic system and has been shown to inactivate inflammatory peptides that play a role in the contact activation of coagulation, such as complement factors C3a and C5a. The full role of TAFI in the hemostatic and innate immune response to sepsis is still under active investigation. Studies suggest that its role as a regulator of fibrinolysis appears to be of prognostic significance similar to that of PAI-1 (ie, elevated levels resulting in decreased fibrinolysis appear to be associated with a poorer outcome in sepsis).[12-14]

Approach to the Patient With an Actual or Suspected Coagulation Disorder

Clinical History

Diagnostic assessment begins at the bedside. The medical history, both past and present, may provide insights into the risk for significant bleeding.[15,16] A prior history of prolonged or excessive bleeding or of recurrent thrombosis is important. Specific questions regarding bleeding should investigate the occurrence of any of the following: spontaneous, easy, or disproportionately severe bruising; intramuscular

hematoma formation (either spontaneous or related to trauma); spontaneous or trauma-induced hemarthrosis; spontaneous mucous membrane bleeding; prior problems with bleeding related to surgery (including dental extractions, tonsillectomy, and circumcision); the need for unanticipated transfusions in the past; menstrual history; and, finally, current medications.

In spite of the decreased general use of aspirin in children, there remain numerous over-the-counter aspirin-containing medications that can potentially interfere with platelet-mediated primary hemostasis. Patients (and parents) may not be aware of the aspirin contained in these products. High doses of over-the-counter and prescription nonsteroidal antiinflammatory medications (eg, ibuprofen, naproxen-sodium) may also impair platelet function. However, unlike aspirin, which produces a noncompetitive inhibition of platelets, the inhibition caused by these other NSAIDs is competitive and resolves once the drug is no longer present. Many of the drugs used in the ICU are also associated with bleeding abnormalities and are discussed later. In trauma situations (either surgical or accidental), it is important to determine the severity of injury relative to the magnitude of bleeding that follows. A prior personal history (or strong family history) of significant thrombosis (eg, deep venous thrombosis, pulmonary embolus, stroke) also suggests the possibility of the presence of a hypercoagulable condition. As thrombotic events are generally uncommon in children, the occurrence of thrombotic events, particularly early cardiovascular events such as myocardial infarction in young adult relatives should cause the clinician to consider the presence of a congenital thrombophilic abnormality in the patient. These abnormalities include antithrombin-III deficiency, PC or S deficiency, the presence of the factor V Leiden R506Q mutation, the prothrombin G20210A polymorphism/mutation, and (possibly) the C677T mutation/polymorphism of the methylenetetrahydrofolate reductase (MTHFR) gene (discussed later). In addition, vasculitis associated with an autoimmune disorder such as systemic lupus erythematosus must always be considered in the evaluation of a child with an unexplained pathologic clot. In all cases, the family history is important in attempting to separate congenital from acquired disorders.

In a general sense, defects in primary or secondary hemostasis can be separated according to the nature of the bleeding. Patients with primary hemostatic defects tend to manifest "capillary-type bleeding"—oozing from cuts or incisions, mucous membrane bleeding, or excessive bruising. This type of bleeding is seen in patients with quantitative or qualitative platelet defects or von Willebrand disease. In contrast, patients with dysfunction of secondary hemostasis (ie, fibrin clot formation) tend to display "large-vessel bleeding," characterized by hemarthrosis, intramuscular hematomas, and the like. This type of bleeding is most often associated with specific coagulation factor deficiencies or inhibitors. However, patients with severe platelet-type defects may also manifest this type of bleeding. Consequently, the presence of only mucosal bleeding is more helpful as this would point to a platelet-type defect affecting mainly primary hemostasis rather than an abnormality of fibrin clot formation (ie, a coagulopathy).

Physical Examination

Development of generalized bleeding in critically ill patients in the ICU presents a special problem. Such bleeding is often a marker of severe underlying multiorgan

system dysfunction. Thus correction of the coagulopathy usually requires improvement in the patient's overall clinical status. Supportive evidence or physical findings of other concurrent organ system dysfunction (eg, renal failure, respiratory failure, hypotension) often are readily apparent. With the exception of massive transfusion syndrome (discussed later), generalized bleeding in critically ill children and infants is often caused by sepsis-related DIC.[17,18] However, the clinician must also consider the coagulopathy of severe liver dysfunction, undiagnosed congenital bleeding disorders (eg, hemophilia, von Willebrand disease), nonaccidental injury, or vitamin K deficiency in newborns or older children with malabsorption in the differential diagnosis.[17-19] In young infants (<3 months of age), the coagulation system is often not yet mature, and prolongation of the prothrombin time (PT) or activated partial thromboplastin time (aPTT) may not reflect an abnormality in hemostasis.[20] Consequently, the intensivist must also take this into consideration when interpreting “abnormal” results. In these cases, consultation with a pediatric hematologist may be indicated.

The physical examination of the patient with a bleeding disorder should address several basic questions. Is the process localized or diffuse? Is it related to an anatomic or surgical lesion? Is the bleeding primarily mucocutaneous? Finally, when appropriate, are there signs of thrombosis (either arterial or venous)? The answers to these questions may provide clues to the cause of the problem (primary versus secondary hemostatic dysfunction).

During the general examination, particular attention should be paid to the presence of several specific physical findings that may be helpful in determining the etiology of a suspected hemostatic abnormality. For example, the presence of an enlarged spleen coupled with thrombocytopenia suggests that splenic sequestration may be a contributor to the observed thrombocytopenia. Splenomegaly accompanied by prolongation of the PT or aPTT may be a consequence of underlying liver disease, whereas splenomegaly in the presence of normal PT and aPTT may indicate that a marrow infiltrative process may be present. Further, evidence of liver disease (eg, portal hypertension, ascites) points to decreased clotting factor synthesis as a possible etiology of a prolonged PT or aPTT. When lymphadenopathy, splenomegaly, or other findings suggestive of disseminated malignancy are detected, acute or chronic DIC should be suspected as the cause of prolonged coagulation times, hypofibrinogenemia, or thrombocytopenia. Purpura that are palpable suggest capillary leak from vasculitis. In contrast, purpura associated with thrombocytopenia or qualitative platelet defects are generally not elevated and cannot be distinguished by touch. Finally, venous and arterial telangiectasia may be seen in von Willebrand disease and liver disease, respectively. When selective pressure is centrally applied to an arterial telangiectasia, the entire lesion fades, whereas a venous telangiectasia requires confluent pressure across the entire lesion (as with a glass slide) for blanching to occur.

Diagnostic Laboratory Evaluation

Before discussion of the appropriate tests that enable the clinician to interpret information from the history, physical examination, or previously obtained (and often confusing) laboratory data, the importance of correct specimen collection for hemostatic evaluation must be emphasized. In the PICU, it is common for laboratory

samples to be drawn through an indwelling arterial or central venous cannula, often because other access is no longer available. Therefore, heparin may be present, either in solutions used to flush the cannula or transduce a waveform or as a component of the IV infusion. Depending on the concentration of heparin in the infusing fluid and the volume of blood withdrawn, several tests can be influenced. Fibrin degradation products (FDPs) can be falsely elevated and fibrinogen falsely low. Likewise, the PT, aPTT, and thrombin time (TT) can be spuriously prolonged. Therefore, a minimum of 20 mL of blood in adolescents and adults (10 mL of blood in younger children) should be withdrawn through the cannula and either discarded or used for other purposes before obtaining a specimen for laboratory hemostasis analysis.[21] This practice should minimize any influence of heparin on the results. In young children and infants, it may not be reasonable to withdraw this volume of blood (even with the use of blood conservation techniques), and a peripheral venipuncture may be necessary. Because the aPTT is sensitive to the presence of small amounts of heparin, the presence of an unexpected prolonged aPTT obtained through a heparinized catheter should raise the suspicion of sample contamination. In this setting, the TT will also be prolonged but will normalize if the contaminating heparin is neutralized (eg, with toluidine blue or Hemasorb).

The presence of most suspected bleeding disorders can be confirmed using routinely available tests, including evaluation of the peripheral blood smear (including an estimate of the platelet count and platelet and red blood cell morphologic features); measurement of the PT, aPTT, and the TT; and assays for fibrinogen, the presence of FDPs, or the D-dimer fragment of polymerized fibrin. This latter test is more specific for the fibrinolytic fragment produced when polymerized fibrin monomer, produced through the action of thrombin on fibrinogen, is cleaved by the proteolytic enzyme plasmin. In contrast, the older assays for FDPs or fibrin split products will be positive even if fibrin is not produced and the fragments are the result of proteolytic degradation of native fibrinogen. Discretion should be used in determining which of these tests are most appropriate for assessment; they need not be ordered as a blanket panel on all patients with known or suspected bleeding disorders. Several major categories of hemorrhagic disorders and the tests that are characteristically abnormal in each are summarized in Table 91.2. In most instances, measurement of the platelet count, fibrinogen level, PT, aPTT, and TT should provide sufficient information for determining the correct diagnosis—or at least for making an educated guess. By using these five screening tests and assessing other, more specific tests only when an absolute diagnosis is necessary, inappropriate use of laboratory resources may be avoided.

TABLE 91.2

Hemorrhagic Syndromes and Associated Laboratory Findings

Clinical Syndrome	Screening Tests	Supportive Tests
Disseminated intravascular coagulation	Prolonged PT, aPTT, TT; decreased fibrinogen, platelets; microangiopathy	(+) FDPs, D-dimer; decreased factors V, VIII, and II (late)
Massive transfusion	Prolonged PT, aPTT; decreased fibrinogen, platelets ± prolonged TT	All factors decreased; (–) FDPs, D-dimer (unless DIC develops); (+) transfusion history
Anticoagulant Overdose		
Heparin	Prolonged aPTT, TT; ± prolonged PT	Toluidine blue/protamine corrects TT; reptilase time normal

Warfarin (same as vitamin K deficiency)	Prolonged PT; ± prolonged aPTT (severe); normal TT, fibrinogen, platelets	Vitamin K–dependent factors decreased; factors V, VIII normal
Liver Disease		
Early	Prolonged PT	Decreased factor VII
Late	Prolonged PT, aPTT; decreased fibrinogen (terminal liver failure); normal platelet count (if splenomegaly absent)	Decreased factors II, V, VII, IX, and X; decreased plasminogen; ± FDPs unless DIC develops
Primary fibrinolysis	Prolonged PT, aPTT, TT; decreased fibrinogen ± platelets decreased	(+) FDPs, (–) D-dimer; short euglobulin clot lysis time
Thrombotic thrombocytopenic purpura	Thrombocytopenia, microangiopathy with mild anemia; PT, aPTT, fibrinogen generally within normal limits/mildly abnormal	ADAMTS13 deficiency/inhibitor, unusually large von Willebrand factor multimers between episodes; mild increase in FDPs or D-dimer
Hemolytic uremic syndrome	Microangiopathic hemolytic anemia, ± thrombocytopenia; PT, aPTT generally within normal limits	Renal insufficiency; FDPs and D-dimer generally (–)

aPTT, activated partial thromboplastin time; *FDPs*, fibrin degradation products; *PT*, prothrombin time; *TT*, thrombin time.

Patients who present with a thrombotic event will generally not display abnormalities of usual "clotting" studies—that is, their PT, aPTT, TT, and fibrinogen will usually be within normal ranges. The finding of a shortened PT or aPTT is not necessarily indicative of a prothrombotic or thrombophilic process being present. Although hyperfibrinogenemia and persistent elevations of F.VIII have been associated with an increased risk of thrombosis, both may be elevated by acute inflammation. Consequently, the finding of elevations of these clotting factors in a patient who has experienced an unexpected thrombotic event may not necessarily indicate that the cause of the event was an elevation in either factor; without prior samples, it is impossible to determine if the elevation is the consequence of the thrombosis or was present prior to its development and potentially causative.

Several inherited or acquired abnormalities that place an individual at increased risk for thrombosis have been identified, and determination of these factors should be undertaken when a thrombotic event is suspected or documented. Prior to initiation of anticoagulation, plasma levels of PC (antigen and activity), protein S (antigen and activity; total and free), and antithrombin-III (antigen and activity) should be obtained. In addition, polymerase chain reaction (PCR) analysis for mutations in the F.V (F.V Leiden; R506Q, and prothrombin [G20210A]) genes should be performed. In addition, a baseline serum homocysteine may be obtained, as the thrombosis risk of the MTHFR mutation may be related to elevations of homocysteine caused by alterations in the metabolism of folic acid rather than the mutation per se. Analysis of population-based data has called into question the prior interpretation that the MTHFR C677T polymorphism/mutation is an independent risk factor for thrombosis in the absence of an elevated serum homocysteine.[22-24] However, as there are numerous well described cases of idiopathic thrombosis occurring in patients for whom the only identified risk factor is the presence of the C677T mutation, it cannot be conclusively stated that the presence of the MTHFR C677T mutation without elevations of serum homocysteine results in no increased risk for pathologic thrombosis. In adult populations, ~40% of patients with thrombosis will not display one of the known thrombophilic risk factors, and it is likely that the percentage in children who are negative for these abnormalities is at least as high or higher. The intensivist must look for confounding clinical conditions, such as dehydration (particularly in the case of central venous sinus thrombosis in infants and young children), indwelling catheters, vascular compression (eg, cervical ribs), type-II heparin-induced thrombocytopenia (see below), and the like in

evaluating a patient with thrombosis.

Potentially Serious Acquired Bleeding Disorders

Disseminated Intravascular Coagulation and Other Microangiopathic Consumptive Disorders

Pathogenesis

Because it often occurs in conjunction with other life-threatening disorders, DIC is one of the most serious hemostatic abnormalities seen in the PICU. The clinical syndrome itself results from the activation of blood coagulation, which then leads to excessive thrombin generation. The result of this process is the widespread formation of fibrin thrombi in the microcirculation, with resultant consumption of certain clotting factors and platelets. Ultimately, this consumption is largely responsible for the development of significant bleeding, as the rate of consumption outpaces the rate at which the clotting factors and platelets are produced.[25] Several specific conditions associated with the development of DIC are presented in Table 91.3. In general, the conditions associated with DIC are the same in adults and children and include a wide variety of disorders, the common feature of which is their ability to initiate coagulation to varying degrees. The mechanisms involved generally can be considered in two categories: (1) those intrinsic processes that enzymatically activate procoagulant proteins and (2) those that cause the release of TF, which then triggers coagulation. These are complex events that can lead to significant bleeding and often complicate the management of an already critically ill child.

TABLE 91.3

Underlying Diseases Associated With Disseminated Intravascular Coagulation

Sepsis	Retained placenta
Liver disease	Hypertonic saline abortion
Shock	Amniotic fluid embolus
Penetrating brain injury	Retention of a dead fetus
Necrotizing pneumonitis	Eclampsia
Tissue necrosis/crush injury	Localized endothelial injury
Intravascular hemolysis	(aortic aneurysm, giant
Acute promyelocytic leukemia	hemangiomata, angiography)
Thermal injury	
Freshwater drowning	Disseminated malignancy
Fat embolism syndrome	(prostate, pancreatic)

Fibrinolysis invariably accompanies thrombin formation in DIC,[25] and thrombin generation or release of the tissue plasminogen activator usually initiates this process. Plasmin is generated and then digests fibrinogen and fibrin clots as they form. Plasmin also inactivates several activated coagulation factors and impairs platelet aggregation. As such, DIC represents an imbalance between the activity of thrombin, which leads to microvascular thrombi with coagulation factor and platelet consumption, and plasmin, which degrades these fibrin-based clots as they form. Therefore, thrombin-induced coagulation factor consumption, thrombocytopenia,

and plasmin generation contribute to the presence of bleeding. Globally, DIC represents an imbalance between clot formation (coagulation) and clot breakdown (fibrinolysis). Initially, DIC is a thrombotic disorder characterized by microvascular thrombosis with bleeding occurring only when the consumption of platelets and clotting factors outpaces the ability to replace these critical elements.

In addition to bleeding complications, the presence of fibrin thrombi in the microcirculation can lead to ischemic tissue injury. Pathologic data indicate that renal failure, acrocyanosis, multifocal pulmonary emboli, and transient cerebral ischemia may be related clinically to the presence of such thrombi. The presence of fibrinopeptides A and B (resulting from enzymatic cleavage of fibrinogen) leads to pulmonary and systemic vasoconstriction, which can potentiate an existing ischemic injury. In a given patient with DIC, either bleeding or thrombotic tendencies may predominate; in most patients, bleeding is usually the predominant problem. However, in up to 10% of patients with DIC, the presentation is exclusively thrombotic (eg, pulmonary emboli with pulmonary hypertension, renal insufficiency, altered mental status, acrocyanosis) without hemorrhage. Whether the presentation of DIC is thrombotic, hemorrhagic, or "compensated" (that is, laboratory results are consistent with DIC without overt bleeding), microthrombosis likely contributes to the development and progression of multiorgan failure.

Clinical Presentation and Diagnosis

DIC is often suspected when there is unexplained, generalized oozing or bleeding; unexplained, abnormal laboratory parameters of hemostasis; or both. This usually occurs in the context of a suggestive clinical scenario or associated disease (see Table 91.3). Although infection and multiple trauma are the most common underlying conditions associated with the development of DIC, certain other organ system dysfunctions predispose to DIC, including hepatic insufficiency and splenectomy.[17,18] Both of these conditions are associated with impaired reticuloendothelial system function and consequent impaired clearance of activated coagulation proteins and fibrin/fibrinogen degradation fragments, which may inhibit fibrin polymerization and clot formation.

The clinical severity of DIC has traditionally been assessed by the severity of bleeding and coagulation abnormalities. Scoring tools that employ a panel of laboratory tests along with severity of illness scores to assess the likelihood and severity of DIC have been proposed in an attempt to determine prognosis at the time of diagnosis to better direct initial therapy. The tests most commonly employed in many of these scoring systems for the diagnosis of DIC are listed in Table 91.4. Although no data exist for pediatric patients, this approach does have prognostic value, particularly in patients with sepsis.[26-28] The more commonly employed scoring systems identify those patients at higher or lesser risk for having DIC based on either a qualitative or quantitative score.[29,30] Although each has been shown to be useful in identifying patients with suspected or confirmed DIC, they have not been fully validated for critically ill children. Limited studies have shown that early identification of DIC, before the onset of a gross hemorrhagic diathesis, improves survival in critically ill children.[29,30]

TABLE 91.4

Laboratory Tests for the Diagnosis of Disseminated Intravascular Coagulation

Test	Discriminator Value
Platelet count	<80-100,000 or a decrease of >50% from baseline
Fibrinogen	<100 mg/dL or a decrease of >50% from baseline
Prothrombin time	>3-sec prolongation above upper limit of normal
Fibrin degradation products	>80 mg/dL
D-dimer	“Moderate” increase

The combination of a prolonged PT, hypofibrinogenemia, thrombocytopenia, and evidence of microangiopathic hemolysis on peripheral blood smear (ie, RBC schistocytes) in the appropriate clinical setting is sufficient to suspect the diagnosis of DIC in most instances. Severe hepatic insufficiency (with splenomegaly and splenic sequestration of platelets) can yield a similar laboratory profile and must be ruled out. In addition to liver disease, several other conditions have presentations similar to DIC and must be considered in the differential diagnosis; they include the coagulopathy of massive transfusion, primary fibrinolysis, thrombotic thrombocytopenic purpura (TTP), atypical hemolytic uremic syndrome (aHUS), heparin therapy, and dysfibrinogenemia.

Although TTP and HUS demonstrate findings consistent with a microangiopathy, the coagulation profile noted with these disorders generally does not strongly suggest DIC. Conversely, the conditions that may present a coagulation profile suggestive of DIC generally do not manifest peripheral blood findings of microangiopathic hemolysis. A comparison of the laboratory findings in these disorders is noted in Table 91.2.

To confirm a diagnosis of suspected DIC, tests that indicate increased fibrinogen turnover (ie, elevated FDPs or D-dimer assay) may be necessary. The D-dimer assay, which measures the D-D fragment of polymerized fibrin, has been shown to be both highly sensitive and specific for proteolytic degradation of polymerized fibrin (fibrin clot that has been produced in the presence of thrombin). Consequently, this test is employed with increasing frequency in patients with suspected DIC and is often stated to be the preferred test of fibrin/fibrinogen consumption. However, remembering that thrombin is produced whenever coagulation is activated in the presence of bleeding, the clinician must interpret a modest elevation of D-dimer in a postoperative or trauma patient with some degree of caution. The presence of a marked elevation of D-dimer in a nonbleeding patient essentially excludes primary fibrinogenolysis as the sole cause of measurable FDPs in the serum. The TT is a less sensitive test for DIC, but it may be useful in cases of suspected heparin overdose, because it corrects in the test tube with the addition of protamine sulfate or toluidine blue. Similarly, the euglobulin clot lysis time may not be sensitive to fibrinolysis associated with DIC but is significantly shortened in most cases of primary fibrino(geno)lysis. Other tests of purported value, such as soluble fibrin monomer or thrombin-antithrombin complex formation, either have problems with sensitivity or are impractical for widespread use outside of a research setting.

Meningococcal Purpura Fulminans

Purpura fulminans is a systemic coagulopathy similar, if not identical, to DIC that classically accompanies meningococcal sepsis and is sporadically noted with other similarly severe infections. The hallmark of this syndrome is tissue ischemia and necrosis due to marked microvascular thrombosis. Patients are generally noted to

have severely depressed levels of PC; the degree of suppression has been shown to correlate with mortality. The presence of the PAI-1 4G/4G genotype associated with the highest plasma levels of PAI-1 has been described in patients with meningococcal sepsis and has been shown to be associated with increased sepsis and mortality but not with an increased incidence of meningococcal meningitis.[13] As mentioned before, APC can stimulate fibrinolysis by forming a tight 1 : 1 complex with PAI-1 thereby leading to inactivation of this fibrinolysis inhibitor. Thus because APC complexes to PAI-1, the reported findings of increased PAI-1 and decreased PC are probably interrelated. High levels of thrombin lead to high levels of APC, APC complexes to PAI-1, and, finally, PC is depleted.[9] This mechanism is possibly the explanation for the extremely low levels of PC found in meningococcal disease. The purpura seen in this disease is similar to that seen in congenital PC deficiency. From a therapeutic point of view, meningococcal sepsis has been considered as a model for sepsis-associated PC deficiency, and many open-label studies of PC replacement therapy have been published in this patient population. The suggestion of one study—that a disturbed activation process of PC on the basis of semiquantitative analysis of expression of thrombomodulin and the endothelial PC receptor in the dermal microvasculature of children with severe meningococcemia and purpuric or petechial lesions[31]—calls into question the benefit of PC concentrates. A randomized, placebo-controlled, dose-finding study of PC concentrate in the same patient population demonstrated adequate activation of PC to APC, even in the most severely ill patients, with a dose-dependent improvement in coagulation parameters following PC replenishment.[32]

Thrombocytopenic Purpura and Hemolytic Uremic Syndrome

Although neither TTP nor HUS generally produces a coagulopathic state, both are characterized by marked microangiopathy and microvascular thrombosis. In spite of this similarity, these two entities are not merely different end points of the same pathophysiologic process manifesting different end-organ effects.[33] HUS is more commonly seen in children and is characterized by a prodrome of fever and diffuse diarrhea (often bloody). Endemic cases of HUS are generally caused by verotoxin expressing enteropathic strains of *Escherichia coli* (O157:H7) or Shigatoxin-expressing strains of *Shigella*. Sporadic cases are generally not associated with diarrhea and are felt to represent atypical HUS resulting from familial defects in complement factor H. Therapy is supportive, including renal replacement measures when indications exist. Although some benefit from plasma exchange has been reported, the role of plasma exchange is unclear. However, aggressive treatment with an anti-complement monoclonal antibody (eculizumab) has been reported to be beneficial in these patients.[33,34]

TTP is characterized by the pentad of microangiopathic hemolytic anemia, thrombocytopenia, neurologic symptoms, fever, and renal dysfunction. Although only 40% of patients will display the full pentad, up to 75% will manifest a triad of microangiopathic hemolytic anemia, neurologic symptoms, and thrombocytopenia. This disorder has been shown to result from the absence of a von Willebrand factor–cleaving protease (ADAMTS-13), resulting in the circulation of unusually large von Willebrand factor multimers that can induce or enhance the pathologic adhesion of

platelets to the endothelium. The therapy of choice for TTP is plasma exchange by apheresis. Platelet transfusions are generally not recommended, except in the case of major bleeding due to the risk of inducing vascular (arterial) occlusion.

Septic patients with thrombocytopenia-associated multiple organ failure (TAMOF) have been described, and in many a decrease in ADAMST-13 has been documented. Intensive plasma exchange by apheresis has been shown to reverse the course of disease and multiorgan failure in many of these children.[35] In some patients, prolongation of PT suggested activation of coagulation and fibrin consumption, and on autopsy patients were noted to have fibrin- and vWf-rich thrombi similar to those seen in classical DIC.

Management

The primary treatment for DIC is correction of the underlying problem that led to its development. Specific therapy for DIC should not be undertaken unless the patient has significant bleeding or organ dysfunction secondary to DIC, significant thrombosis has occurred, or treatment of the underlying disorder (eg, acute promyelocytic leukemia) is likely to increase the severity of DIC.

Supportive therapy for DIC includes the use of several component blood products.[36,37] Packed red blood cells are given according to accepted guidelines in the face of active bleeding. Fresh whole blood (ie, <24–48 hours old) may be given to replete both volume and oxygen-carrying capacity, with the potential additional benefit of providing coagulation proteins, including fibrinogen and platelets. FFP is of limited value for the treatment of significant hypofibrinogenemia because of the inordinate volumes required to make any meaningful contribution to plasma fibrinogen concentration. Cryoprecipitate contains a much higher concentration of fibrinogen than does whole blood or fresh frozen plasma (FFP) and therefore is more likely to provide the quantity of fibrinogen necessary to replenish fibrinogen that is consumed by DIC. Commercial fibrinogen concentrate contains even greater amounts of fibrinogen (by volume) than does cryoprecipitate and has the advantage of being processed to reduce the risk of viral transmission and also enables the clinician to infuse a known amount of fibrinogen. FFP infusions may effectively replete other coagulation factors consumed with DIC, such as PC, although the increase in these proteins may be quite small unless large volumes of FFP are infused. The use of cryoprecipitate or FFP in the treatment of DIC has been open to debate in the past because of concern that these products merely provide further substrate for ongoing DIC and thus increase the amount of fibrin thrombi formed. However, clinical (autopsy) studies have failed to confirm this concern.

The goal of blood component therapy is not to produce normal "numbers" but rather to produce clinical stability. If the serum fibrinogen level is <75 to 50 mg/dL, repletion with cryoprecipitate (or fibrinogen concentrate) to raise plasma levels to ≥100 mg/dL is the goal. A reasonable starting dose is 1 bag of cryoprecipitate for every 10 kg of body weight every 8 to 12 hours. As cryoprecipitate is not a standardized component (ie, its content varies from bag to bag), the fibrinogen level should be rechecked after an infusion to assess the increase. The amount and timing of the next infusion is then adjusted according to the results. Infusions of commercial fibrinogen concentrate are dosed based on the formula included in the manufacturer's package insert. Platelet transfusions also may be used when thrombocytopenia is thought to contribute to ongoing bleeding. Many of the

fibrin/fibrinogen fragments produced in DIC have the potential to impair platelet function by inhibiting fibrinogen binding to platelets, which may be clinically significant at the concentration of FDPs achieved with fulminant DIC. Platelet transfusions in patients with DIC should be considered to maintain platelet counts up to 40,000 to 80,000/uL depending on the clinical specifics of the patient. In the case of children with sepsis-associated TAMOF and low ADAMST-13, plasma exchange may represent an intervention that is simultaneously supportive and therapeutic.

Pharmacologic therapy for DIC has two primary aims: to "turn off" ongoing coagulation so that repletion of coagulation factors may begin and to impede thrombus formation and ensuing ischemic injury. Recombinant activated factor VII (rhF.VIIa), a recombinant hemostatic factor, has been used to treat bleeding in DIC refractory to other therapies as well as in trauma and in other medical and surgical causes of severe, life-threatening bleeding. Most of these studies have demonstrated efficacy in the control of hemorrhage, but most have not demonstrated a decrease in mortality.[38-41] With the exception of those patients with acquired inhibitors to F.VIII, no controlled trials have been conducted in children. Recombinant activated factor VII has also been shown to correct the hemostatic defect caused by the antiplatelet agents aspirin and clopidogrel.[42] Reports have noted that use of rhF.VIIa may result in an increase in thrombosis and thromboembolic events, although the incidence appears to be small and the severity of most events mild.[43]

Various synthetic and natural modulators of hemostasis have shown some efficacy in moderating multiorgan dysfunction in animal models of sepsis. These include anticoagulant molecules (eg, heparin, antithrombin III, tissue factor pathway inhibitor [TFPI], activated protein C [APC]) and thrombolytic modulators (eg, tissue plasminogen activator [tPA], thrombin-activatable fibrinolysis inhibitor [TAFI]). Although initial reports of the use of recombinant human APC in sepsis demonstrated a benefit on survival in septic adults, there was increased bleeding in the elderly, and the pediatric trial was stopped because of futility and increased bleeding in infants. Subsequent reanalysis of data demonstrated no benefit of this agent in the treatment of sepsis and it was withdrawn from the US market. Clinical trials addressing the use of other natural modulators of thrombosis and fibrinolysis have not consistently demonstrated benefit in septic patients,[44-48] although results from ongoing clinical studies (particularly in Japan) continue to show some benefit worth exploring.[49]

Liver Disease and Hepatic Insufficiency

Abnormal Hemostasis in Liver Disease

Liver disease is a common cause of abnormal hemostasis in patients in the ICU, with abnormal coagulation studies or overt bleeding occurring in ~15% of patients who have either clinical or laboratory evidence of hepatic dysfunction. It is a common cause of a prolonged PT or aPTT, often without any clinical sequelae. The hemostatic defect associated with liver disease is multifactorial, with multiple aspects of hemostasis being affected.[50,51] In liver disease, synthesis of several plasma coagulation proteins, including factors II, V, VII, IX, and X, is impaired. Fibrinogen synthesis by the liver is usually maintained at levels that prevent bleeding until terminal liver failure is present. Factor VIII and von Willebrand factor levels are

generally normal to increased in acute and chronic liver disease.

In addition to these deficiencies in plasma coagulation protein synthesis, many patients with liver disease, particularly cirrhosis, have increased fibrinolytic activity. Increase in fibrinolysis potential is a frequent occurrence in patients who have undergone portacaval shunt procedures. The mechanism for this heightened fibrinolytic state is not clear, although increased amounts of plasminogen activator can often be demonstrated. It may be difficult to discern whether fibrinolysis occurs solely because of underlying severe liver disease or as a result of concurrent DIC, as patients with cirrhosis are at increased risk for the development of DIC. The clinical distinction can be virtually impossible if active bleeding is present. In liver disease, increased levels of FDPs may result from increased fibrinolysis and by decreased hepatic clearance.

Thrombocytopenia may be present to a variable degree in patients with hepatic dysfunction—usually ascribed to splenic sequestration. It is rarely profound and as a solitary defect generally does not produce clinically significant bleeding. In vitro platelet aggregation is often affected, however. Increased plasma concentrations of FDPs are a possible cause of these abnormalities. The thrombocytopenia of liver disease in conjunction with other coagulation/hemostatic defects secondary to liver disease may result in bleeding that is difficult to manage, particularly if all aspects of the problem are not addressed.

Patients with synthetic liver disease may also exhibit decreased synthesis of the vitamin K–dependent anticoagulant proteins protein C and protein S, as well as antithrombin III.[51] Decreased levels of these natural anticoagulants may increase the risk of thrombosis. The PT, aPTT, and TT will not be affected by the levels of any of these naturally occurring anticoagulants.

Many clinicians utilize the international normalized ratio (INR) as a surrogate measure of the PT. The INR was developed to compare the intensity of vitamin K antagonist (VKA) anticoagulant therapy between clinical labs employing reagents of differing sensitivities, and, although it is calculated from the PT, it is not a surrogate for the PT. It has only been standardized and validated for the purpose of quantifying the intensity of VKA anticoagulation. As INR is calculated from the PT, any condition that produces a prolonged PT will give an increased INR. Many clinicians have assumed that the presence of an elevated INR indicates an increased risk for bleeding, as in a patient on vitamin K antagonist therapy. However, no data exist to confirm this assumption. Multiple studies on patients with liver disease and prolonged PT have demonstrated maintenance of thrombin generation and increased risk for thrombosis rather than an increased risk of bleeding.[52-55] Some of these studies have documented a decrease in fibrinolytic potential in liver disease by thromboelastography presumably accounting for the increased risk of thrombosis. However, other investigators have shown an increase in global fibrinolytic potential in patients with liver disease, but this finding has not been linked to an increase in bleeding.[56] The lack of correlation of PT (and consequently INR) with bleeding risk in patients with liver disease may be explained by the fact that, in contrast to vitamin K antagonist therapy in which only one pathway involved in hemostasis is affected, liver disease has effects on essentially all phases of hemostasis: primary (platelet-dependant) hemostasis, fibrin clot initiation, coagulation inhibition, and fibrinolysis. Of these, the PT and (coincidentally) the INR measure only fibrin clot production. The net result of these multiple effects is a “rebalancing” of hemostasis in patients

with liver disease. As a consequence, neither the PT (nor INR) accurately reflects the risk of bleeding in these patients.[57-60] However, patients with liver disease may still experience clinically significant bleeding as a consequence of severe thrombocytopenia, a rebalanced hemostatic system that does not adequately compensate for a decrease in procoagulant clotting factors or increased fibrinolysis. Anatomic lesions such as esophageal varices due to portal hypertension also represent a significant risk for upper gastrointestinal hemorrhage in these patients. Consequently, the intensive care clinician must carefully and thoroughly assess his or her patient for these risks. However, the role traditional measures of coagulation (ie, PT, aPTT) play in this assessment is limited at best.

Presentation

The hemostatic defect in liver disease is multifactorial, and each patient should be approached accordingly. The most common scenario is a patient with liver disease and a prolonged PT without overt bleeding in whom the potential for bleeding is a concern. In patients with liver disease and impaired synthetic capabilities, particularly those who are critically ill, F.VII activity levels are usually the first to decrease due to its short half-life of 4 to 6 hours and increased turnover, which results in a prolonged PT and can be noted even when usual markers of hepatocellular injury/hepatic insufficiency remain relatively normal.[50,51] A prolonged TT in the setting of liver disease may indicate the presence of dysfibrinogenemia as a result of altered hepatic fibrinogen synthesis. As the severity of liver disease increases, the aPTT may also be affected, reflecting more severely impaired synthetic function. In this setting, plasma concentrations of the vitamin K–dependent coagulation proteins decrease, as do those of F.V (which is synthesized in the liver but not vitamin K dependent). Although fibrinogen synthesis occurs in the liver, its plasma level is maintained until the disease approaches end stage. When fibrinogen levels are severely depressed as a consequence of decreased synthesis and not increased degradation (fibrinolysis) or consumption (conversion to fibrin), liver failure has typically reached the terminal phase.

In more severe forms of liver disease, fibrinolysis may complicate clinical management. The differentiation between concomitant DIC and fibrinolysis attributable to liver disease alone may be difficult. The D-dimer assay result should be negative in the patient who has liver disease, elevated FDPs, and fibrinolysis but no active bleeding because thrombin is not being generated. Further clinical distinction usually is not possible, and in practice it is difficult to distinguish between a patient with fibrinolysis alone and not activation of coagulation and one who has a DIC-like process.

Management

If the patient is not actively bleeding, no specific therapy is required, with certain provisos. In patients with a prolonged PT who are in a postoperative state or are scheduled for an invasive procedure, correction of the PT may be considered; FFP is the component of choice for this purpose. However, studies have shown inconsistent and incomplete correction of the PT in liver disease and also call into question the need to correct this parameter at all. Multiple studies have shown that invasive procedures can be performed safely without correction of a prolonged PT.[57,61,62]

When a correction of the PT is desired, a decrease of the PT to a value ≤3 seconds above the upper limit of normal for the testing lab is considered adequate.[62-64]

Supplementation of fibrinogen, in the form of cryoprecipitate or fibrinogen concentrate, is required only if fibrinogen levels are <50 to 100 mg/dL or if significant dysfibrinogenemia is documented. Vitamin K deficiency is also relatively common in this patient population, and replacement may be necessary. In contrast to children with dietary vitamin K deficiency and normal liver function, correction of the PT in vitamin K–responsive critically ill patients typically requires longer than 12 to 24 hours. Patients with significant hepatic impairment may manifest a partial response or may not respond at all. The immediate use of FFP prothrombin complex concentrates (PCC) is therefore appropriate when rapid correction is necessary. rhF.VIIa infusions have been shown to control bleeding in severe liver disease, although reduced mortality does not necessarily result.[65,66] To date, no studies have conclusively shown rhF.VIIa concentrate to be superior to prothrombin complex concentrates (PCCs) for the management of bleeding.[67]

When the synthetic capability of the liver becomes more profoundly impaired and the aPTT is prolonged, greater volumes of FFP or more specific therapy may be necessary. The use of F.IX concentrates (prothrombin complex concentrates; PCC) or rhF.VIIa has been advocated, particularly if bleeding is present. The products produced from plasma pooled from multiple donors carry a relatively low but still measurable risk of hepatitis (both types B and C) and HIV. In addition, they may initiate thromboembolic events, provoke DIC, and worsen hemostasis.[68] A comprehensive therapeutic approach is required in the patient with active bleeding as a result of liver disease. Initially, FFP, 10 to 15 mL/kg body weight, may be given every 6 to 8 hours until bleeding slows significantly; it should then be continued at maintenance levels as dictated by clinical status and coagulation studies. Continuous infusions of FFP (starting dose 2–4 mL/kg/hr) have also been used with success to control bleeding following a bolus infusion.[69] rhF.VIIa or prothrombin complex concentrates may be used in those patients who are unresponsive to FFP infusions.[66,70] PCCs containing three factors (F.II, IX, X) and four factors (F.II, VII, IX, X) are the preferred products for those patients who do not manifest a good response to FFP infusions as greater amounts of clotting factors can be infused in smaller volumes when compared to FFP. However, if therapy is designed to replace a known deficiency of a factor not contained in a pooled concentrate, then FFP infusion is indicated. Cryoprecipitate, or commercial fibrinogen concentrate, should be infused for fibrinogen levels <50 to 100 mg/dL. Platelet transfusions also may be required if the platelet count is <40 to 80,000/μL, depending on the clinical situation. Vitamin K should be empirically administered on the presumption that part of the synthetic defect may result from a lack of this cofactor. However, a poor response to vitamin K in the presence of severe liver disease should be anticipated. Transfusions of packed cells are administered as deemed appropriate by the clinician.

Vitamin K Deficiency

The most common cause of a prolonged PT in the ICU is vitamin K deficiency. Vitamin K is necessary for the γ-carboxylation of factors II, VII, IX, and X, without which these factors cannot bind calcium and are not efficiently converted into their activated forms. F.VII has the shortest half-life of these coagulation proteins;

accordingly, the PT is the most sensitive early indicator of vitamin K deficiency.

Vitamin K deficiency is relatively common in critically ill patients for several reasons, including the use of broad-spectrum antibiotics, poor nutrition preceding or subsequent to ICU admission, and the use of parenteral nutrition without vitamin K supplementation. Many of the second- and third-generation cephalosporins directly interfere with vitamin K absorption from the gut lumen. The metabolites of these antibiotics may even act as competitive inhibitors of vitamin K. In addition, these and other antibiotics may kill or inhibit the growth of gut bacteria and limit the amounts of vitamin K that they normally produce and excrete into the gut lumen. Although malnutrition also may contribute to the development of vitamin K deficiency, it usually requires 1 to 2 weeks to develop in the complete absence of vitamin K intake. However, the use of parenteral alimentation without vitamin K supplementation coupled with antibiotic use may result in rapid vitamin K depletion, and prolongation of the PT can occur within only 2 to 3 days. Finally, fat malabsorption states, including cystic fibrosis, may be associated with vitamin K deficiency. Vitamin K is fat soluble and is not absorbed well in some conditions of biliary tract and intrinsic small bowel disease. In the ICU, vitamin K deficiency usually results from the interaction of several of these factors and is rarely limited to only one of the conditions mentioned. It is the responsibility of the clinician to maintain an awareness of the potential for vitamin K deficiency and to treat accordingly.

The differential diagnosis of an isolated prolongation of the PT, with or without bleeding, includes both vitamin K deficiency and liver disease. The clinical presentation of these patients is often quite similar. In fact, the distinction sometimes can be made only on the basis of the response (or lack thereof) to empirical vitamin K therapy. Warfarin administration (either overt or covert) also should be excluded as a cause of a prolonged PT. Newer, long-acting vitamin K antagonist rodenticides (so-called "superwarfarin"), which when ingested, produce a profound, prolonged, vitamin K–resistant reduction in vitamin K–dependent clotting factors, may produce an isolated prolongation of the PT initially. Treatment of poisoning with these agents requires aggressive, prolonged use of vitamin K and, in the bleeding patient, support with 4-factor PCC, FFP infusions, or rhF.VIIa. Confirmation of warfarin exposure as the cause of a prolonged PT is possible by toxicologic methods to detect the drug or its metabolites or the presence of non-carboxylated forms of vitamin K–dependent clotting factors (**p**roteins **i**nduced by **v**itamin **K** **a**ntagonist; PIVKAs) in plasma. In addition, the presence of a specific inhibitor or congenital deficiency of F.VII will also result in an isolated prolongation of the PT. Acquired inhibitors of F.VII are rare, and homozygous deficiency of F.VII has not been described. Individuals who are heterozygous for F.VII deficiency tend to have F.VII levels in the 25% to 35% range and do not appear to be at significant increased risk for bleeding. Lupus-like anticoagulants that result from inflammation may also lead to an isolated prolongation of the PT; these are generally of no clinical significance and are not associated with an increased risk of bleeding.

Infants who fail to receive vitamin K in the immediate postnatal period may develop a systemic coagulopathy manifested by bruising and gastrointestinal bleeding, generally occurring between 1 and 2 weeks of age. The first manifestation is often prolonged bleeding following circumcision. Infants with malabsorption or breast-fed infants who ingest medications that interfere with vitamin K in breast

milk may develop similar manifestations beyond 2 weeks of age.

The laboratory findings of an isolated vitamin K deficiency, in addition to a prolonged PT, include a normal fibrinogen level, platelet count, and F.V level. F.V is not a vitamin K–dependent protein and should therefore be normal, except in cases of DIC (consumption) or severe liver disease (decreased production). Prolongation of the aPTT from vitamin K deficiency, warfarin therapy, or liver disease is a relatively late event and occurs initially as a result of F.IX depletion.

Management

The management of vitamin K deficiency consists primarily of its repletion, usually by IV or subcutaneous routes in critically ill patients. Therapy should not await the development of bleeding or oozing but should be administered when the PT abnormality is detected and vitamin K deficiency is thought to be responsible. As with other drugs administered subcutaneously (eg, insulin), adequate blood pressure and subcutaneous perfusion are necessary to ensure reliable absorption from the soft tissues. Concern exists regarding the possibility of anaphylactoid reactions with the IV use of vitamin K. This risk is minimized when the drug is given as a piggyback infusion over 30 to 45 minutes in a small volume of fluid rather than as a bolus or “slow-push” dose; IV-piggyback infusion is the preferred method of drug administration in hemodynamically unstable patients. The usual dose of vitamin K in children is 1 to 5 mg IV or subcutaneously (up to 10 mg in larger children). In an otherwise healthy person, the PT should correct within 12 to 24 hours after this dose. However, serial dosing of critically ill patients is often utilized, and the PT may require up to 72 hours to normalize. If the PT does not correct within 72 hours after three daily doses of vitamin K, intrinsic liver disease should be suspected. Further administration of vitamin K is of no additional benefit in this setting.

When the patient is actively bleeding, it is not sufficient to give vitamin K alone. A more immediate restoration of coagulation is required. FFP has traditionally been employed in this setting. To restore hemostasis to an acceptable level (30%-50%) of normal enzyme activity, 10- to 15-mL/kg body weight of FFP is typically required. A similar approach is used in patients who were previously given warfarin. rhF.VIIa (15–20 mcg/kg) has been used with success to reverse the bleeding noted in vitamin K deficiency and in warfarin overdose.[39,66,70,71] Four-factor PCCs that contain significant amounts of F.VII are effective in correcting both PT and aPTT values in these patients and have become the treatment of choice to correct a patient with warfarin overdose–associated bleeding.[68]

Iatrogenic Coagulopathy

Massive Transfusion Syndrome

Transfusion of large quantities of blood can result in a multifactorial hemostatic defect. The genesis of this problem is related to the “washout” of plasma coagulation proteins and platelets, and it may be exacerbated by the development of DIC with consequent factor consumption, hypothermia, acidosis, or rarely, by citrate toxicity or hypocalcemia. These variables often act in combination to cause a coagulopathic state.[72]

A washout syndrome can result from the transfusion of large amounts of stored blood products that are devoid of clotting factors and platelets and develops exclusively in patients who receive large volumes of packed red blood cells (eg, trauma victims, patients with massive gastrointestinal hemorrhage or hepatectomy, or those undergoing cardiopulmonary bypass) without also receiving FFP and platelets. Factors V and VII have short shelf half-lives and are often deficient in blood that has been banked longer than 48 hours. In addition, a qualitative platelet defect can be demonstrated in whole blood within hours of its storage, especially if an acid-citrate-dextrose solution is used. Consequently, transfusion of large quantities of stored whole blood may produce limited improvement in the bleeding that results from decreased clotting factors and platelets. The development of a washout coagulopathy is directly dependent on the volume of blood transfused relative to the blood volume of the patient. As a general rule, residual plasma clotting activity after single-blood-volume exchange falls to 18% to 37% of normal; after a double-blood-volume exchange, residual activity is only 3% to 14% of normal; and after a triple-blood-volume exchange, <5% of normal clotting function remains.

The patient who is bleeding as a consequence of massive transfusion or washout presents with diffuse oozing and bleeding from all surgical wounds and puncture sites. Laboratory abnormalities include prolonged PT, aPTT, and TT. Fibrinogen levels and platelet counts are typically decreased; FDPs are not usually increased unless concurrent DIC is present (see Table 91.2). The likelihood that the clinicolaboratory picture is a direct result of the massive transfusion can be estimated from the amount of bleeding that has occurred and the blood volume that has been administered relative to the patient's blood volume (ie, the number of blood volume exchanges that have been given). The more stored blood (eg, packed red blood cells) transfused relative to the patient's blood volume, the greater the chance of the development of coagulopathy due to massive transfusion.

Management

Children with severe trauma frequently present with massive bleeding and acidosis secondary to hypoperfusion (see also Chapter 118). Aggressive transfusion support through the implementation of a formal transfusion protocol that would provide multiproduct support with red blood cells (RBCs), plasma, and platelets in a set ratio closer to 1 : 1 : 1 has been hypothesized to improve the outcome in these children.[74-77] However, to date prospective studies have not clearly demonstrated an improvement in outcome, and concern for an increase in transfusion-related organ dysfunction exists. However, blood product use and blood bank–related costs have been shown to be less with such transfusion regimens. Some centers have investigated the use of rotational elastometry to guide blood product transfusion in trauma patients.[3,71-73] Although this methodology offers the potential advantage of evaluating several different aspects of hemostasis and not merely fibrin clot formation (as is measured by the PT and aPTT), these methods have not yet been widely accepted in clinical practice.

Prospective identification of those at risk to develop a coagulopathy from massive transfusion is important. When the magnitude of the insult and the anticipated need for blood are large, both platelets and FFP should be given before a coagulopathy develops; the exact ratio of packed red blood cells to other blood components (ie, platelets, plasma, or cryoprecipitate) to prevent the development of massive

transfusion coagulopathy has not been established.[78-80] However, studies in adults suggest that 1 unit of FFP for every unit of packed RBCs transfused effectively replaces plasma clotting factors.[81] In larger children (eg, weight ≥30 to 40 kg or body surface area ≥1 m^2), half of a unit of apheresis-collected platelets (generally equivalent to 4 to 5 units of platelets derived from whole blood donation) and 1 unit of FFP should be given for each 5 units of whole blood or packed cells transfused. In smaller children, 10 mL/kg of platelets and 10- to 15-mL/kg FFP should be given for each 40 to 50 mL/kg of blood transfused. These amounts should prevent washout and its attendant bleeding. The therapeutic approach to patients who develop a coagulopathy from massive transfusion is supportive.

Anticoagulant Overdose

Anticoagulant therapy is not unusual in the PICU, and the possibility of errors in administration exists. Methods of prophylactic anticoagulant use, systemic anticoagulation, and thrombolytic therapy are sometimes poorly standardized and can lead to overdose.

Heparin

Heparin is a repeating polymer of two disaccharide glycosaminoglycans and is commercially prepared from either porcine intestinal mucosa or bovine lung. Heparin is currently available in two types of preparations: unfractionated heparin (UH) and low-molecular-weight heparin (LMWH). It is important to understand the differences between these two forms of the drug, as they have different mechanisms of action and associated precautions. UH has an immediate effect on coagulation that is mediated primarily through its association with antithrombin III. The resulting heparin-antithrombin III complex possesses a much greater affinity for thrombin than antithrombin III alone, and it inactivates thrombin, thereby damping down clot formation. In addition, heparin has an anti-F.Xa effect that is also dependent on an association with AT-III, although this represents a smaller anticoagulant component. Achieving a therapeutic aPTT with UH is very difficult in the face of low levels of antithrombin III. The degree of anticoagulation produced by heparin is monitored by the prolongation of the aPTT. In contrast, LMWH, produced by controlled enzymatic cleavage of heparin polymers, affects anticoagulation almost exclusively through inhibition of F.Xa. This also requires association with AT-III, but the anticoagulant effect is less dependent on variation in AT-III plasma levels. Consequently, a more stable degree of anticoagulation is produced. Due to its longer half-life (~3–5 hours) and biological activity (~24 hours), LMWH allows for intermittent bolus therapy (ie, every 12 or 24 hours) while maintaining a steady-state effect. However, LMWH does not produce consistent prolongation of the aPTT and requires assay of anti-Xa activity for monitoring.

Heparin is metabolized in the liver by the heparinase enzyme in a dose-dependent fashion, with excess heparin then being excreted through the kidneys. As the rate of heparin administration is increased, the half-life of the drug is prolonged due the increase in the percentage of the drug being excreted by the kidney. For example, when a 100-U/kg bolus of heparin is infused IV, the average half-life of the drug is 1 hour. If the bolus is increased to 400 or 800 U/kg, the half-life is prolonged to 2.5 and 5 hours, respectively. The nonlinear response results in greater drug effects on

coagulation with smaller dosage increments. When one “re-boluses” or increases a heparin infusion rate in response to insufficient anticoagulation (ie, inadequate prolongation of the aPTT), a point will be reached when further small increments in the heparin infusion rate may result in a substantially greater prolongation of the aPTT. The risk of pathologic bleeding associated with heparin increases when the prolongation of the aPTT is beyond the therapeutic window (generally considered to be 1.5–2.5 times the patient's baseline aPTT, corresponding to a plasma heparin concentration of 0.2–0.4 units/mL or anti-Xa level of 0.3–0.7 units/mL). As a corollary, administration of heparin as a continuous infusion rather than in an intermittent bolus dose regimen is less likely to be associated with pathologic bleeding.

Management

Serious bleeding associated with heparin overdose can be rapidly reversed by protamine sulfate. Protamine binds ionically with heparin to form a complex that lacks any anticoagulant activity. As a general rule, 1 mg of protamine neutralizes ~100 U of heparin (specifically, 90 US Pharmacopeia (USP) units of bovine heparin or 115 USP units of porcine heparin). The dose of protamine required is calculated from the number of units of active heparin remaining in the patient's system. This, in turn, is estimated from the original heparin dose and the typical half-life for that infusion rate. The aPTT is used to gauge the residual effects of heparin. During and after cardiopulmonary bypass surgery, the activated clotting time (ACT) is frequently used to measure the heparin effect and to judge the effectiveness of and need for protamine neutralization. This methodology is sometimes employed in the ICU. However, the equipment used for this measurement is poorly standardized and different systems give different results.[82] Consequently, care must be taken when employing one of these methods in the ICU.

Protamine itself potentially has anticoagulant effects, and precautions are necessary during its administration. The drug should be given by slow IV push over 8 to 10 minutes. A single dose should not exceed 1 mg/kg (50-mg maximum dose). This dose may be repeated, but no more than 2 mg/kg (100-mg maximum dose) should be given as a cumulative dose without rechecking coagulation parameters. The dose of protamine should always be monitored by coagulation studies. Significant side effects are most commonly seen in situations of overly rapid drug administration and include hypotension and anaphylactoid-like reactions. The allergic reactions to protamine represent type I anaphylactic reactions between an antigen (protamine) and antibody (IgE or IgG) and result in histamine release. Consequently, H2 blockers have been shown to be effective in treating and minimizing these reactions. In addition, complement activation, thromboxane, and nitric oxide production have all been shown to play some role in the pathogenesis of these reactions.[83,84] Risk factors for protamine hypersensitivity reactions include prior exposure to protamine, insulin-dependent diabetes (with NPH exposure), fish allergy, and vasectomy. In that LMWH is not predictably neutralized by protamine, invasive procedures should not be performed within 24 hours of administration. Bleeding following LMWH therapy has been treated effectively with rhF.VIIa.

Warfarin

Warfarin and vitamin K are structurally similar in their respective 4-hydroxycoumarin nucleus and naphthoquinone ring. The mechanism of action of warfarin is through competitive inhibition of vitamin K epoxide reductase, which is necessary to regenerate the reduced form of vitamin K. This form of vitamin K is a necessary cofactor in the postribosomal modification of the vitamin K–dependent coagulation proteins (factors II, VII, IX, and X) γ-carboxylation. This postsynthetic modification produces a calcium-binding site on the molecule, which, when occupied, allows for the efficient activation of the zymogen clotting factor into its enzymatically active form. When warfarin is present in sufficient plasma concentrations, the active (γ-carboxylated) forms of vitamin K–dependent factors are depleted.

The PT (INR) is an accurate indicator of the effects of warfarin when its use has continued beyond 2 or 3 days. F.VIIa (the active form) has a half-life of only 4 to 6 hours and is rapidly depleted after one or two doses of warfarin. The remainder of the vitamin K–dependent factors may take up to a week to become depleted. The PT becomes prolonged with F.VII depletion alone but does not reflect an overall state of anticoagulation until an equilibrium period of several days has passed, generally once the INR is at or near target value for 2 to 3 days. Over this interval, the other vitamin K–dependent factors become depleted, and PT prolongation, as measured by the INR, can then be used to assess the anticoagulant effects of warfarin. In severe cases of warfarin overdose, the aPTT also becomes prolonged as a result of a marked reduction of the active forms of factors II, IX, and X.

Several drugs and pathophysiologic conditions are associated with potentiation of warfarin's effects on coagulation. Many of the drugs known to prolong the effects of warfarin are listed in Table 91.5. These drugs have a variety of mechanisms that generally include either inhibition of function or competitive binding of the enzymes that are responsible for active warfarin metabolism. Aspirin does not seem to have any direct influence on warfarin metabolism but so profoundly influences qualitative platelet function that it increases the bleeding risk resulting from warfarin's anticoagulant effects. The same is true for clofibrate. Ingestion of large doses of aspirin may also impair prothrombin (F.II) synthesis, further increasing the effects of warfarin administration. Warfarin is metabolized by the liver. Conditions of acute and chronic hepatic dysfunction can alter warfarin metabolism and vitamin K–mediated γ-carboxylation of the vitamin K–dependent coagulation proteins. Broad-spectrum antibiotics also may limit vitamin K availability through their alteration of the gut flora (in addition to any direct effect on vitamin K metabolism). All of these factors may ultimately influence a patient's response to warfarin.

TABLE 91.5

Drugs That Potentiate the Anticoagulant Effects of Warfarin

Antibiotics
Broad-spectrum antibiotics (especially cephalosporins)
Griseofulvin (oral)
Metronidazole
Sulfonamides
Trimethoprim-sulfamethoxazole
Antiinflammatory Drugs
Steroids (anabolic, in particular)
Acetylated salicylates
Phenylbutazone (oxyphenbutazone)

Sulfinpyrazone	
Other Drugs	
Clofibrate	
Disulfiram	
Phenytoin	
Thyroxine (both D- and L-isomers)	
Tolbutamide	

A clinical syndrome referred to as "warfarin (Coumadin) necrosis" has been noted during the initial stages of anticoagulation with a vitamin–K antagonist. It is characterized clinically by the development of skin and subcutaneous necrosis, particularly in areas of subcutaneous fat, and pathologically by the thrombosis of small blood vessels in the fat and subcutaneous tissues. This syndrome is caused by the rapid depletion of the vitamin K–dependent, anticoagulant PC prior to achieving depletion of procoagulant proteins and occurs predominantly in individuals who are heterozygous for PC deficiency. Although anticoagulation generally requires a decrease in procoagulant protein levels to ~20% to 25%, a prothrombotic milieu is created with PC levels of ≤40%. Consequently, individuals who are heterozygous for PC deficiency and have baseline PC levels of 50% to 60% may develop a prothrombotic environment during the first few days of warfarin therapy. The risk of developing warfarin necrosis appears to be greater when an initial dose of warfarin >10 to 15 mg is administered. The development of this syndrome generally can be avoided if heparin and warfarin therapy are overlapped until "coumadinization" is complete and if large loading doses of warfarin (>15 mg) are avoided.

Management

When over-anticoagulation with warfarin presents with bleeding, immediate reversal is usually mandated.[71] The treatment of choice is FFP, which provides prompt restoration of the deficient vitamin K–dependent coagulation proteins, along with restoration of hemostatic function. Ten to 15 mL/kg of FFP is usually sufficient to produce significant correction of the PT, although repeat infusions of FFP may be necessary for continued correction of the PT due to the short half-life of F.VII.[78] Vitamin K also may be administered, particularly in situations that are less acute although this will make it more difficult to "recoumadinize" the patient afterward. For severe bleeding or bleeding not controlled by FFP infusions, rhF.VIIa and 4-factor PCC have been used successfully (see the "Vitamin K Deficiency" section, presented earlier). The "3-factor" PCCs currently available in the United States are not approved for the treatment of factor VII deficiency (either congenital or secondary to VKA treatment) owing to the limited amount of F.VII contained in them.[68]

Platelet Disorders

Platelets are necessary for efficient clot formation. They not only produce a physical barrier at the site of vascular injury (the so-called "platelet plug"); they also serve to focus the clotting process at the point of bleeding by delivering vasoconstrictors, clotting factors to the bleeding site, and provide a surface on which clot development occurs (see Fig. 91.3). Quantitative and qualitative platelet disorders are a common cause of clinical bleeding in the PICU. An overview of platelet disorders based on

this classification scheme is presented in Table 91.6.

TABLE 91.6

Platelet Disorders Seen in the Intensive Care Unit

Quantitative	Qualitative
Increased Destruction	Drugs
Immune	Antiinflammatory agents
Idiopathic thrombocytopenic purpura	Aspirin (irreversible)
Systemic lupus erythematosus	Nonsteroidal antiinflammatory agents
Acquired immunodeficiency syndrome	Corticosteroids Antibiotics Penicillins (eg, ampicillin, carbenicillin, ti.carcillin, penicillin-G)Cephalosporins (eg, cephalothin)
Drugs (gold salts, heparin, sulfonamides, quinidine, quinine) Sepsis	
Nonimmune	
Thrombotic thrombocytopenic purpura/hemolytic uremic syndrome	Nitrofurantoin Chloroquine, hydroxychloroquine Phosphodiesterase inhibitors Dipyridamole Methylxanthines (eg, theophylline) Other drugs Antihistamines α-blockers (eg,phentolamine) β-blockers (eg, propranolol) Dextran Ethanol Furosemide Heparin Local anesthetics (eg, lidocaine) Phenothiazines Tricyclic antidepressants Nitrates (eg, sodium nitroprusside, nitroglycerin)
Mechanical destruction (eg, cardiopulmonary bypass, hyperthermia)Consumption (ie, disseminated intravascular coagulation)	
Decreased Production	
Marrow suppression	
Chemotherapy	
Viral illness (eg, cytomegalovirus Epstein-Barr virus, herpes simplex, parvovirus) Drugs (thiazides, ethanol, cimetidine) Marrow replacementTumor Myelofibrosis Other conditions Splenic sequestration Dilution (see massive transfusion syndrome)	
	Metabolic Causes
	Uremia
	Stored whole blood
	Disseminated intravascular coagulation (ie, fibrin degradation product-mediated inhibition)
	Hypothyroidism

Quantitative Platelet Disorders

A decrease in the number of circulating platelets reflects the presence of increased peripheral destruction or sequestration, decreased marrow production, or a combination of these factors. Examples of increased peripheral destruction include immune-mediated processes (both autoimmune and drug induced), abnormal consumption (as in DIC), and mechanical destruction (eg, cardiopulmonary bypass, hyperthermia). Autoimmune processes such as idiopathic thrombocytopenic purpura (ITP; now referred to as immune thrombocytopenia), systemic lupus erythematosus, or acquired immunodeficiency syndrome can result in increased peripheral destruction and increased splenic sequestration of platelets. Autoimmune destruction also may occur in conjunction with lymphocytic leukemia or lymphoma.

The prototypic example of immune thrombocytopenia is ITP, in which immunoglobin (generally IgG) directed against specific platelet antigens results in platelet destruction by a cell-mediated mechanism. Acute ITP is usually self-limited; in contrast, chronic ITP generally requires immunosuppressive therapy to maintain an acceptable platelet count. Although life-threatening bleeding may occur in either acute or chronic ITP, it is a rarity; the incidence of intracranial hemorrhage in ITP is estimated to be less than 1%, and in most series it is between 0.1 and 0.2%.[85,86] Most episodes of severe bleeding occur when the platelet count is less than 10 to

20,000/uL, but a decision to institute therapy should be based on the overall clinical setting and not just the platelet count. Steroids may be given (2–4 mg/kg/day of prednisone or its equivalent). High doses of IV γ-globulin (1–2 g/kg given over 2–5 days) and infusions of anti-RhD antigen antibody (WinRho; 25–60 mcg/kg) are equally efficacious in producing at least transient elevations in platelet counts. Note, however, that WinRho should only be used in patients who are Rh (+) and have a functioning spleen. Agents such as vincristine/vinblastine, cyclophosphamide, and, with increasing frequency, rituximab (anti-CD20 monoclonal antibody) also have been used as immunosuppressants, with variable success, although responses are generally not immediate. Splenectomy may be required to avert serious bleeding complications in patients who do not respond to medical management, although this approach is chosen much less often in children than in adults. In ITP, the degree of bleeding attributed to thrombocytopenia is generally less than that noted when thrombocytopenia results from decreased platelet production. In general, severe bleeding is not noted until the platelet count is <10,000/μL, although levels below 40,000 to 50,000/uL may increase the risk of bleeding associated with invasive procedures. The use of thrombopoietin-like drugs to stimulate platelet production in chronic ITP generally does not play a role in the management of immune thrombocytopenia in the ICU, as platelet counts only demonstrate a significant increase after several weeks of therapy.

The development of drug-induced, immune-mediated platelet destruction should always be considered in the thrombocytopenic PICU patient. When present, it is usually reversible; withdrawal of the offending drug prevents further immune-mediated platelet destruction. The exact mechanism of platelet destruction may be related to the binding of drug to the platelet membrane, with subsequent binding to the platelet, platelet-drug complex, or both, of a specific antibody. The resulting platelet-drug-antibody complexes are then cleared by the reticuloendothelial system (eg, the spleen), and thrombocytopenia develops. Drugs used in the ICU that are most commonly associated with this clinical picture include quinidine, quinine, heparin, gold salts, various penicillin and cephalosporin antibiotics, and the sulfonamides. The anticonvulsant valproic acid frequently produces a dose-dependent thrombocytopenia that is, at least in part, immunologic in nature.

A variety of drugs are associated with the nonimmune development of thrombocytopenia by bone marrow suppression. Most cancer chemotherapeutic agents produce thrombocytopenia as a consequence of marrow suppression. The thiazide diuretics, cimetidine, ethanol, and several of the cephalosporin and penicillin antibiotics may suppress platelet production. Generalized infection (such as bacterial sepsis) and many viral illnesses are also associated with bone marrow suppression and thrombocytopenia, even if an element of immune platelet destruction is present. Disorders such as Gaucher disease may produce a mild-to-moderate thrombocytopenia as a result of marrow replacement by nonhematopoietic cells.

Consumption of platelets can also cause thrombocytopenia. Mechanical destruction invariably occurs during cardiopulmonary bypass or the use of ventricular assist devices. It is not uncommon to note a 50% drop in platelet count postbypass when compared to preoperative platelet levels. Platelet counts generally recover toward preoperative levels by 48 to 72 hours after bypass. The high body temperatures seen in severe hyperthermic syndromes may also destroy platelets,

and they are consumed during microvascular coagulation in DIC. In many of these circumstances, the thrombocytopenia may be the sole or a contributing cause of significant bleeding.

Heparin-Induced Thrombocytopenia

Heparin is widely used in ICUs to maintain vascular access or as a therapy for acute thrombosis. Exposure to heparin may result in thrombocytopenia and in a small number of cases this may result in arterial thrombosis. Thrombocytopenia may develop upon exposure to heparin in one of two ways. Acute nonidiosyncratic thrombocytopenia is seen in 10% to 15% of patients who receive heparin. The degree of thrombocytopenia is usually mild and usually remits despite continued use of the drug. This has previously been referred to as type I heparin-induced thrombocytopenia (HIT). The thrombocytopenia results from the direct binding of the heparin molecule to the platelet surface, does not involve an immune mechanism, and has no clinical significance. Heparin need not be stopped in these patients. Idiosyncratic HIT is of much greater clinical consequence. Although it is a less frequent occurrence (typically seen in <5% of patients who receive heparin), it has a much greater potential for clinical morbidity. Arterial thrombosis is the most significant risk of this form of HIT (previously referred to as type II HIT) and may be life threatening, causing myocardial infarction, cerebrovascular accident, pulmonary embolism, or renal infarction. The thrombosis is the consequence of the deposition of platelet aggregates in the microcirculation.[87,88] Thrombocytopenia in this disorder involves the formation of platelet aggregates mediated by the binding of a specific antibody, directed against a heparin-platelet factor-4 complex, to platelets in the presence of heparin. This results in the activation of platelets and appears to require minuscule amounts of heparin. Clinical bleeding is an infrequent problem in these patients. Severe thrombocytopenia (ie, <15–20,000/μl) is unusual in this disorder.

From a practical perspective, the diagnosis of HIT is usually one of exclusion. Clinical scoring systems to assess the probability of HIT have been developed, but they are more useful for identifying those individuals who are less likely to have HIT and are less sensitive in their ability to accurately identify patients with HIT.[89,90] None of these scoring systems have been validated in pediatric patients. Diagnostic markers do exist (eg, heparin-dependent platelet antibodies, platelet aggregation, or serotonin release), but these tests are best considered confirmatory and not exclusionary. An ELISA assay for heparin-dependent platelet antibodies is the most common test obtained to investigate a possible diagnosis of HIT, but because of a relatively high "false-positive" rate, it is generally recommended that a more specific heparin-induced platelet injury assay, such as a serotonin release assay, be performed for confirmation. The diagnosis may be difficult to recognize because coexisting clinical illnesses with the potential to cause thrombocytopenia also may be present. Although HIT may be more likely to be associated with the use of bovine lung heparin, it can occur after exposure to porcine heparin or, much less commonly, LMWH. When type II HIT is suspected or confirmed, all exposure to heparin, including heparin flushes, heparin in total parenteral nutrition, and heparin-coated catheters, must be removed, and anticoagulation with an alternate agent must be initiated because of the risk of delayed thrombosis, which can occur up to 30 days after removal of heparin exposure.[88,91] Patients with type II HIT should receive

continued anticoagulation with direct thrombin inhibitors (argatroban, bivalirudin) or with the heparinoid danaparoid (currently not available in the United States). Production of the direct thrombin inhibitor lepirudin was discontinued in 2012 and is no longer available. Although anti-Xa agents, such as fondaparinux, may also be used, the direct thrombin inhibitors are preferred, as they carry no risk of cross-reacting with the heparin-dependent antibodies already present.[91,92] Of the members of this class of anticoagulants, bivalirudin is gaining increasing preference for anticoagulation in children at high risk for or with suspected or documented HIT.[93-97] Bivalirudin is largely cleared by proteolysis in the plasma; argatroban is cleared by the liver and lepirudin by the kidney. Consequently, the choice and dose of drug may be affected by the presence of hepatic or renal insufficiency. Although there are pharmacokinetic and safety data for use in children for bivalirudin and argatroban, there are no similar data pertaining to the use of lepirudin in children.[98,99] Warfarin alone is not adequate therapy for suspected type II HIT because of the risk of thrombosis from depression of PC levels. However, warfarin can be utilized in conjunction with a direct thrombin inhibitor and subsequently continued as a single agent once therapeutic suppression of vitamin K–dependent clotting factors has been achieved.

Qualitative Platelet Disorders

Many of the drugs frequently used in the ICU have the potential to impair platelet function. Frequently, the sicker patients are more likely to be exposed to one of these drugs. These patients often have other underlying pathophysiologic conditions that in and of themselves can predispose to bleeding. An abbreviated list of the drugs that can affect at least in vitro platelet function is presented in Table 91.6.

All unnecessary drugs should be viewed as suspect and discontinued in patients with evidence of qualitative platelet dysfunction or in those in whom it is strongly suspected. In most cases, terminating the offending drugs usually restores normal platelet activity. Aspirin is a notable exception as it irreversibly inhibits platelet cyclooxygenase, resulting in a defect that lasts for the duration of the platelet life span (8–9 days). The effect is profound: A single 325-mg aspirin tablet results in a qualitative platelet defect that remains in 50% of the circulating platelets 5 days after its ingestion. Ideally, all aspirin ingestion should be avoided for at least 7 days prior to an elective invasive procedure. New drugs that target the adenosine diphosphate $P2Y_{12}$ receptor on the surface of platelets (eg, clopidogrel, prasugrel, ticagrelor) also produce a prolonged inhibition of platelet reactivity that may last up to 2 weeks following discontinuance of the drug depending on the duration of therapy.[100]

Nonsteroidal antiinflammatory agents similarly affect the platelet cyclooxygenase enzyme. However, their effects are reversible, and normal platelet function is usually restored within 24 hours of the last dose. Under most circumstances, the degree of platelet inhibition produced by these agents is not clinically significant, and patients can receive these drugs for analgesia and fever control. However, it is reasonable to minimize their use in the bleeding severely thrombocytopenic patient. The β-lactam antibiotics can sterically hinder the binding of a platelet aggregation agonist (eg, adenosine diphosphate [ADP]) to its specific platelet receptor, resulting in impaired platelet aggregation under circumstances of normal physiologic stimulation. This, too, is reversed on removal of the drug. Fortunately, only a minority of patients

exposed to these antibiotics will exhibit clinically significant platelet inhibition.

In the PICU, the possibility must always be considered that a patient with bleeding suggestive of a platelet defect might have an inherited disorder of platelet function. Though rare, these disorders are encountered from time to time and include Glanzmann thrombasthenia (abnormal platelet GPIIb/IIIa), Bernard-Soulier syndrome (abnormal GP Ib/IX), Wiskott-Aldrich syndrome, platelet storage pool deficiency (abnormal platelet-dense bodies), and the gray platelet disorder (abnormal platelet α-granules). Individuals with vitamin C deficiency (scurvy) or those with collagen disorders (eg, Ehlers-Danlos syndrome) will present with mucocutaneous bleeding but have normal platelet number and in vitro function. The defect in these conditions is the production of abnormal collagen that is unable to support platelet adhesion, resulting in poor clot initiation and tensile strength. Vitamin C deficiency is an acquired defect in collagen structure, whereas Ehlers-Danlos syndrome is congenital. Individuals with scurvy typically have hypertrophied purpuric gums, whereas those with Ehlers-Danlos syndrome (and related disorders) have a lifelong history of joint dislocations and poor wound healing. Individuals with von Willebrand disease will also present with mucocutaneous bleeding, but many will also have a variably prolonged aPTT as a result of the secondary decrease in F.VIII in this disease.

Management

Because many of the adverse drug-related platelet effects are reversible, all unnecessary medications should be discontinued promptly when platelet function seems impaired. The more controversial issue is deciding whether platelet transfusions are warranted in a particular patient. The relationship of thrombocytopenia to clinical bleeding is relative—that is, it is difficult to identify a specific, arbitrary platelet count (threshold) below which bleeding is likely to occur. Several conditions, such as massive transfusion syndrome and DIC, may respond to empirical platelet transfusion at counts as high as 80,000 or even 100,000 platelets/uL, although significant bleeding in the presence of a platelet count of 40,000 to 50,000/uL (or greater) is unlikely to be a result of the thrombocytopenia. With other causes such as thrombocytopenia seen with cancer chemotherapy and bone marrow aplasia, prophylactic therapy may not be required until counts fall below 10,000 to 20,000/uL. As previously stated, rhF.VIIa has been used to reverse the hemostatic defect caused by aspirin or clopidogrel.[42]

The morbidity and mortality related to bleeding increase measurably in patients who undergo induction chemotherapy for acute leukemia when the platelet count falls below 10,000 to 20,000/uL. Empirical administration of platelets to these patients significantly limits both morbidity and mortality. This finding has resulted in the practice of most patients receiving cancer chemotherapy receiving prophylactic platelet transfusions once their platelet count falls below this threshold. However, the application of this practice for all other patients with platelet counts in this range is unclear. A major concern that should temper the empirical use of platelet transfusion is the development of alloimmunization to transfused platelets, potentially negating any future benefit from platelet transfusion in a time of need. Patients with aplastic anemia appear to have a particularly high incidence of platelet alloimmunization following transfusion. Patients with autoimmune disorders

associated with increased peripheral platelet destruction, drug-related thrombocytopenia, and disorders causing splenic sequestration are unlikely to benefit from platelet transfusion and routine platelet transfusions should be avoided. An exception is related to planned, invasive procedures with an increased risk of bleeding. In this situation, empirical platelet transfusion immediately before the procedure may be reasonable.

Uremia

Uremia is commonly seen in the ICU and is associated with an increased risk of bleeding.[101,102] Uremia has been shown to cause a reversible impairment of platelet function, although the "toxin" responsible for this defect is not well defined.[103] Some studies have demonstrated an impairment of platelet-vessel wall interactions and suggest defects in von Willebrand factor. The degree of platelet impairment appears to be related to the severity of uremia for a given patient. In addition, thrombotic events are also increased in patients with uremia. These, too, appear to be multifactorial in etiology but in part reflect the increased renal loss of antithrombin III and protein S in nephritic-range proteinuria.[102]

Several therapeutic approaches may modulate the qualitative platelet defect associated with uremia. The primary therapy in this setting is dialysis. Cryoprecipitate, 1-deamino-8-D-arginine vasopressin (DDAVP; 0.3 mcg/kg, maximum dose 21 mcg), and conjugated estrogens (10 mg/day in adult patients) have been given with good results to patients with severe uremia and an acquired defect in primary hemostasis. The benefit derived by treatment with cryoprecipitate or DDAVP appears to be related to the consequent increase in the plasma concentration of the large multimeric forms of von Willebrand factor, thus greatly improving platelet adhesion. However, the duration of action of these agents is limited, reaching their zenith at between 2 and 6 hours. Additional doses of DDAVP during the same 24-hour period may result in a diminished response to the drug (tachyphylaxis) with little or no further benefit. Patients who exhibit tachyphylaxis to DDAVP may require 48 to 72 hours before again responding to this agent. Repeated administration of DDAVP may result in significant hyponatremia, particularly in infants and young children. The mechanism of action of the conjugated estrogens is not known. In contrast to infusion of cryoprecipitate or DDAVP, the effect of estrogen is more protracted and does not diminish with repeat dosing, although a benefit is frequently not apparent until 3 to 5 days after therapy begins.

Selected Disorders

Systemic Diseases Associated With Factor Deficiencies

Patients with amyloidosis, Gaucher disease, or nephrotic syndrome are occasionally admitted to the pediatric ICU for the care of a severe acute illness. Each may have one or more associated factor deficiencies that may complicate patient management and result in bleeding. Patients with either amyloidosis or Gaucher disease may develop F.IX deficiency. F.X deficiency has also been associated with amyloidosis.

These deficiencies generally result from the adsorption of the specific clotting factor by the abnormal proteins present in each disorder. In the nephrotic syndrome, F.IX deficiency may develop. Although it was originally thought that proteinuria was responsible for the development of F.IX deficiency, this does not appear to be the case. The deficiency typically remits with corticosteroid therapy.

CHAPTER 92

Thrombosis in Pediatric Intensive Care

Sally Campbell, Paul Monagle

PEARLS

- Vascular access devices are the most common cause of thromboembolic disease in children, and every attempt should be made to limit their use based on real clinical need.
- Thrombophilia is rarely the major cause of thrombosis in critically ill children, and multiple tests to identify thrombophilic states are rarely useful to patient management.
- For reasons that remain uncertain, heparin-induced thrombocytopenia is rarely seen in children.
- Care must be taken in the diagnosis of thrombosis in children, as assumptions made in adult diagnostic strategies may not be true in children.
- Unfractionated heparin is the most useful anticoagulant in critically ill children; however, dosing errors are common, and pediatric intensive care units should spend considerable resources on training and systems to ensure safe management of heparin.

Dramatic improvements in pediatric intensive care have led to the improved survival of critically ill children and to the emergence of previously rare complications. To achieve this improved survival, there has been a dramatic increase in the invasiveness of supportive care. The use of central venous access, invasive arterial monitoring, and circulatory support including ventricular assist devices (VADs) and extracorporeal membrane oxygenation (ECMO), as well as processes such as hemofiltration and hemodialysis that are performed through large-bore vascular access devices, will increase the likelihood of vascular endothelial damage or direct vascular obstruction. These insults to the vascular system are often combined with prolonged hypotension, systemic inflammatory states, and infection, all of which may alter endothelial and vascular responsiveness. Finally, a multitude of drugs and fluids are administered during the periods of critical illness, which can impact directly on plasma proteins and endothelial function or which may lead to

dilution of critical plasma proteins involved in the coagulation system. Not surprisingly, therefore, thromboembolism is an increasingly common problem faced in the pediatric intensive care unit (PICU) setting, and it contributes significantly to morbidity and mortality.

This chapter describes key issues related to thrombosis in the PICU. Developmental hemostasis is a crucial concept both to the understanding of the etiology of thrombosis in children and to the application of diagnostic and therapeutic strategies. The etiology, epidemiology, clinical features, diagnosis, and management of the major types of thrombosis encountered in children in the PICU will be discussed. However, thromboses of the central nervous system (CNS), including arterial ischemic stroke and cerebral sinovenous thrombosis, are beyond the scope of this chapter (see Chapter 69). As in many areas of pediatrics, high-level evidence is often lacking; however, best-available evidence will be drawn upon where possible. Extrapolation from adult studies resulting in suboptimal treatment outcomes in children highlights the need for pediatric-specific trials and guidelines.

Developmental Hemostasis

The hemostatic system is a dynamic, evolving entity that not only affects the frequency and natural history of thromboembolic disease in children but also the response to therapeutic agents.[1-5] The global functioning of the coagulation system in neonates and children is different from that in adults, as are the plasma levels of many coagulation proteins. Overall the levels of most coagulation proteins increase with age, and neonates compared with adults have significantly lower levels of these proteins.[6] The exceptions are FV, FVIII, FXIII, and vWF, which are elevated at birth compared with adults. In addition to quantitative differences, there is evidence (mostly from animal models) of qualitative differences in many coagulation proteins, especially in neonates.[7,8] Although ongoing research in this area is desperately needed, current knowledge regarding the differences between adults and children in plasma proteins most likely to impact on anticoagulation therapy is as follows.

Plasma concentrations of antithrombin (AT) are physiologically low at birth (~0.50 U/mL) and do not increase to adult values until 3 months of age. Sick premature neonates frequently have plasma levels of AT of less than 0.30 U/mL. This likely has a profound effect on the action of heparin, whose antithrombotic activity is dependent on the catalysis of AT to inactivate specific coagulation enzymes, in particular thrombin. Some studies suggest children in pediatric intensive care units have markedly reduced AT levels compared to age-matched controls, potentially further enhancing this effect (Fig. 92.1). The capacity of plasmas from neonates to generate thrombin is both delayed and decreased compared to adults, and it is similar to plasma from adults receiving therapeutic amounts of heparin.[9] Both an increased sensitivity and an increased resistance to unfractionated heparin's anticoagulant activities have been reported in vitro in plasma from neonates. Increased sensitivity to unfractionated heparin is observed in systems based on assays dependent on thrombin generation (eg, activated partial thromboplastin time [APTT]). The in vitro effects of unfractionated heparin (0.25 U/mL) on neonates, children, and adults were compared, and thrombin generation was delayed and reduced in children compared to adults and virtually absent in neonates.[10] Resistance to unfractionated heparin is observed in systems based on assays that

measure the inhibition of exogenously added factor Xa or thrombin and that are dependent on plasma concentrations of AT.

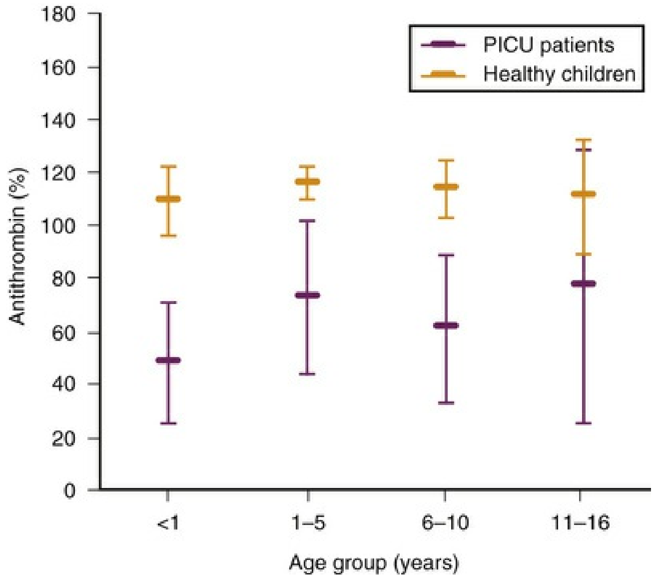

FIG. 92.1 Antithrombin levels by age group in samples obtained from children in a pediatric intensive care unit (PICU) compared to age-matched controls. Note the reduction in antithrombin levels in sick children. (Courtesy P. Monagle.)

In vitro, thrombin generation is similar in adults and children at the same concentration of low-molecular-weight heparin (LMWH). However, at 0.25 U/mL LMWH, thrombin generation was delayed and reduced by approximately half in newborns compared to adults. These differences were matched by reductions in rates of prothrombin consumption.[10]

The vitamin K–dependent clotting factors are the most extensively studied group of factors in infants. Factors II, VIII, IX, and X have been demonstrated to be one-half to one-third of that of adults, despite receiving vitamin K prophylaxis at birth. The levels of the vitamin K–dependent factors and the contact factors (factors XI and XII, prekallikrein, and high-molecular-weight kininogen) gradually increase to values approaching adult levels by 6 months of life. For children receiving vitamin K antagonists, the capacity of their plasmas to generate thrombin is delayed and decreased by 25% compared to plasmas from adults with similar international normalized ratios (INRs).[11]

Whether the overall activity of the protein C/protein S system varies with age is unknown. However, at birth, plasma concentrations of protein C are very low, and they remain decreased during the first 6 months of life. Although total amounts of protein S are decreased at birth, functional activity is similar to that in the adult because protein S is completely present in the free, active form because of the absence of C4-binding protein.[12,13] Furthermore, the interaction of protein S with activated protein C in newborn plasma may be regulated by the increased levels of α_2-macroglobulin. Plasma concentrations of thrombomodulin are increased in early childhood and decrease to adult values by the late teenage years. However, the influence of age on endothelial cell expression of thrombomodulin has not been

determined.[14]

Despite the changes in individual protein levels and in global tests of coagulation, the hemostatic system in neonates and children does not seem disadvantageous compared to the "normal" coagulation system as measured in adults. There are no data to support either an increased bleeding or thrombotic risk during infancy and childhood for any given stimulus; on the contrary, one could argue that the hemostatic system in neonates and children is protective against bleeding and thrombotic complications compared to adults. This is despite the fact that when considering individual proteins, many proteins exist at levels during stages of infancy that would be associated with disease in adults. There clearly remains much to be learned about the evolution of the coagulation system with age, and this is an area in which there is much ongoing active research. As a better understanding of the neonatal and child coagulation system is achieved over coming years, thinking may change regarding many aspects of thrombosis development and management in this patient population.

Etiology and Epidemiology

Unlike adults, 95% of venous thromboembolism (VTE) cases in children are secondary to an identifiable risk factor,[15] and although there are a variety of risk factors to consider, perhaps the most useful concept for the clinician to understand remains the Virchow triad.[16] The Virchow triad recognizes that three factors are involved in the development of thrombosis: the blood vessel wall, the blood constituents, and blood flow[17] (Fig. 92.2). Patients in the PICU often demonstrate abnormalities in one, two, or all of these factors, and the recognition of this information can be a useful guide to therapy. For example, in a patient with a cardiac lesion, either primary or postsurgical, where there is extremely poor blood flow in one part of the cardiovascular system, the optimal management is to improve the blood flow. Although anticoagulation may have an important role, progressively increasing the intensity of anticoagulation will significantly increase the risk of bleeding and yet may not substantially further reduce the risk of thrombosis, which is being driven primarily by flow. Alternatively, patients with disseminated intravascular coagulation (DIC) have a marked perturbation of function of the vascular endothelium; therefore anticoagulation alone is unlikely to prevent thrombotic complications, which will only be avoided by treatment of the primary illness and subsequent resolution of the DIC.

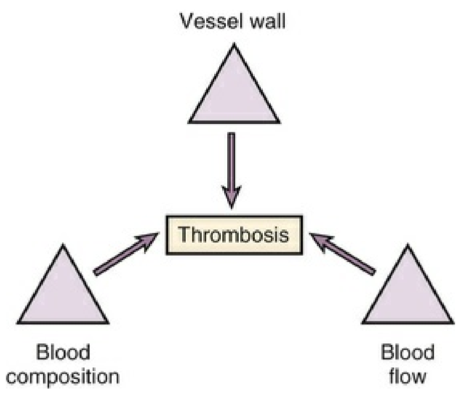

FIG. 92.2 Virchow's triad, highlighting the importance of each factor in contributing to thrombosis formation.

Combinations of these factors are important in many instances. For example, central venous access is a common precipitant of thrombosis, most typically through interruption to flow (especially in small infants where the catheter-to-vein diameter ratio is close to 1 : 1) and through disruption of the vessel wall at the insertion site. However, thrombosis is seen more commonly when there is an additional abnormality in the blood constituents as well, for example, in protein-losing states like nephrotic syndrome or enteropathy, through inflammatory or septic conditions, or via drugs such as oral contraceptives. Consideration of the etiologic factors in this way often enables clinicians to make some attempt at risk stratification and to modify care to reduce some of the multifactorial drivers of thrombosis on an individual basis, even though there may not be clear numeric data from large studies on the actual level of risk.

Table 92.1 summarizes the epidemiology and known risk factors for most etiologies of common non-CNS thrombosis seen in critically ill children. The most important risk factors for thrombosis in the pediatric intensive care unit remain the presence of vascular access devices and recent cardiac surgery. Two additional risk factors worth discussing, although they are not often particularly relevant in children, are thrombophilias and heparin-induced thrombocytopenia.

TABLE 92.1

Summary of the Epidemiology, Clinical Features, Diagnosis, and Complications of the Most Common Types of Non-CNS Thromboembolism in Children

	Type/Location	Age/Sex	Incidence	Underlying Illness or Risk Factors	Clinical Features	Diagnosis	Con
Spontaneous VTE	Lower limb	M = F Teenagers	1.2 per 10,000 hospital admissions		Leg, inguinal, or abdominal pain Leg swelling or discoloration	Doppler US	Imm PE Car exte
	Axillary	M = F Teenagers	Very rare	Mass lesion Thoracic inlet obstruction New sport involving arms	Arm swelling, pain, and discoloration	Doppler US	Chy SVC syn Lon Rec VTE PPS
CVAD-related VTE	Line tip thrombosis	Higher in neonates		Cancer, sepsis, trauma, surgery, immobility, long-term lines, congenital heart disease, burns, cardiac catheterization	Inability to flush or draw from line	Linogram Echocardiogram if tip in RA	Vari hem
	Fibrin sleeve				Asymptomatic	Linogram, venography	
	CVAD-related DVT Iliofemoral, IVC, jugular, subclavian		1%-75%		Asymptomatic Limb or facial swelling, pain, discoloration SVC syndrome, chylothorax	Doppler US for neck, limb, and abdominal TE Venography (radiograph, CT, or MR) for intrathoracic TE	
PE			Up to 30% children with CVC-related DVT	CVAD-related DVT RA thrombus, cancer, CHD, cardiomyopathy, burns, sepsis, trauma,	Asymptomatic (up to 50%) Tachycardia Chest pain Respiratory distress Increased oxygen	V/Q scan Pulmonary angiography Plain radiography, CT, MR ECG	Dea Pul hyp and fail Rec

				nephrotic syndrome, APLA, transplantation	requirements Acute right heart failure Collapse Sudden death	Autopsy most common diagnostic test in children	
Arterial TE	Peripheral arterial catheter Radial artery, occasionally foot arteries			Peripheral arterial catheter	Acute limb ischemia: blanching, pallor, diminished pulses/CR Loss of patency	Doppler US	Isch (har

Central Venous Access Devices

The most common risk factor for venous thrombosis in children appears to be the presence of a central venous catheter (CVC), although most children have several concomitant risk factors.[18] Over 50% of venous thromboembolisms in children occur in the upper venous system secondary to the use of CVCs. Three types of CVC-related thrombosis are described in the literature: clots at the tips of CVCs that impair infusion or withdrawal of blood; fibrin sleeves that are not adherent to vessel walls but may occlude CVCs; and CVC-related thrombi that adhere to vessel walls, with partial or complete obstruction of vessels where the CVC is located. This discussion refers to this third type of thrombosis only—that is, obstructive CVC-related thrombosis. A number of mechanisms may contribute to the development of CVC-related thrombosis, including damage to the vessel wall by the CVC or by substances infused through the CVC (total parenteral nutrition [TPN], chemotherapy), disrupted blood flow due to the presence of the CVC, and thrombogenic catheter materials. The use of CVCs occurs most commonly in children who require short-term intensive care, hemodialysis, or long-term supportive care (TPN or chemotherapy).[16]

The incidence of CVC-related thrombosis reported in the literature varies, reflecting differences in underlying conditions, diagnostic tests, and index of suspicion. A prospective cohort study, which was looking at clinically symptomatic thrombus only in the PICU, quoted a risk of 74 clinically symptomatic VTE per 10,000, which is a significant rise from previous studies that quoted between 5 and 55 per 10,000.[19] Even this number is likely an underestimation of the incidence, as previous studies demonstrated that <50% of VTE are symptomatic. In many patient populations, the incidence is not accurately known. Many PICUs have been attempting to create a risk stratification protocol to allow for more targeted prophylaxis, but in the absence of good data about risk factors this practice remains speculative. This issue will be discussed in more detail later in the chapter.

The role for thromboprophylaxis in CVCs remains uncertain, and as yet there is no current recommendation for routine systemic prophylaxis for short- to medium-term CVC. One of the many issues with studying this area is the difference in nomenclature about "prophylaxis." VTE prophylaxis with unfractionated heparin (UFH) or LMWH is often confused with "line prophylaxis" or "line patency prophylaxis" (usually UFH but at very different doses).

Arterial Access

The most common type of arterial thrombosis in children occurs as a result of placement of arterial catheters. Non–catheter-related arterial thrombosis may be congenital (familial hyperlipidemia and hyperhomocysteinemia) or acquired (Takayasu arteritis, Kawasaki disease, congenital heart disease, and arterial thrombosis in transplanted organs). There are, in general, three types of arterial

catheterizations that are used in children that may result in arterial thrombosis: umbilical arterial catheterization in neonates (which will not be discussed in this chapter), cardiac catheterization, and peripheral catheterization. Arterial occlusion causes tissue ischemia resulting in tissue necrosis if the vascular occlusion persists. Organ and tissue damage at remote sites may result from embolic events occurring due to fragmentation of the original thrombus.

Often, in the PICU, short-term femoral artery access will be required, emergency femoral artery puncture will be performed, or, alternatively, the femoral artery will be inadvertently accessed during attempts at femoral venous access. In terms of understanding the implications of this approach, one can only really extrapolate from the cardiac catheterization literature, recognizing that diagnostic and therapeutic cardiac catheterization via the femoral artery have significant differences in terms of thrombosis risk.

Adverse events occurring as a result of femoral artery puncture include arterial spasm and arterial thrombosis. Clinically, vascular spasm and thrombosis are indistinguishable in the initial phases of presentation with the following symptoms: decreased or absent pulses, pale or mottled limb, and decreased capillary refill. Arterial spasm usually resolves within a few hours in the absence of therapy, whereas arterial thrombosis usually requires therapy. The incidence of femoral artery thrombosis following cardiac catheterization without thromboprophylaxis is approximately 40%. The incidence is inversely proportional to patient age and weight, with infants at highest risk.[20] The frequency of femoral artery thrombosis in PICUs is unclear. Similarly with peripheral arterial catheterization, the mechanism of injury is endothelial damage and blood vessel occlusion. The exact frequency of peripheral arterial occlusion in the PICU remains unknown.

Cardiac Surgery

Children with congenital heart disease constitute a major proportion of children seen in tertiary hospitals with thrombosis. Data show that almost 50% of infants less than 6 months old and 30% of older children who suffer venous thromboembolic disease have underlying cardiac disorders. Similarly, almost 70% of infants (less than 6 months) and 30% of children who suffer arterial thrombosis have underlying cardiac defects. In addition, the majority of children receiving primary anticoagulant prophylaxis are being treated for complex congenital heart disease or severe acquired cardiac illness.[20] Presumably, the mechanisms underlying this increased risk of thrombosis are alterations to blood flow (for example, following Fontan surgery, where venous return is driving the pulmonary blood flow) and disturbances of the vascular endothelium related to intravascular sutures or vascular manipulation. Whether a postsurgical inflammatory state induces changes in the blood constituents that predispose to thrombosis is also unknown. Two classic examples of cardiac surgery–related thrombosis are the Blalock Taussig (BT) shunt and the Fontan procedure.

The natural history of BT shunts has been assessed using angiography. Godart and colleagues[21] assessed BT shunt growth and development of stenosis and distortion in 78 patients at a mean follow-up time of 51 months. They found that growth of the pulmonary arteries occurred but did not exceed the normal growth of the pulmonary arterial tree. However, a shunt procedure could cause distortion and

stenosis of the pulmonary artery that might have important implications for future corrective surgical intervention. Risk factors for patency and stenosis include the age of the patient and graft size.[22,23]

The incidence of thrombotic occlusion of BT shunts in the literature ranges from 1% to 17%.[24-27] This risk might be increased in children having first-stage Norwood surgery, as these children are small and unstable and often have labile blood pressures as well.

There have been a number of reviews regarding anticoagulation after Fontan surgery.[28,29] The Fontan procedure, or a modified version, is the definitive palliative surgical treatment for most congenital univentricular heart lesions. Thrombosis remains a major cause of early and late morbidity and mortality. Reported incidences of venous thrombosis and stroke ranged from 3% to 16% and 3% to 19%, respectively, in retrospective cohort studies where thrombosis was the primary outcome, and from 1% to 7% in retrospective studies assessing multiple outcomes. Thrombosis may occur anytime following Fontan procedures, but it often presents months to years later. No predisposing factors have been identified with certainty, although this may be due to inadequate power and the retrospective nature of the studies.

Thrombophilia

Congenital thrombophilia is usually defined as having the following features: (1) positive family history, (2) early age of onset of thromboembolism, (3) recurrent disease, and (4) multiple or unusual thrombosis locations. Clinically, the most significant inherited prothrombotic conditions are deficiencies of antithrombin (AT), protein C (PC), and protein S (PS), because of the large increase in relative risk these deficiencies confer. Activated protein C resistance/factor V Leiden (FV-R506Q) and prothrombin G20210A (IIG20210A) polymorphism, while having less impact on individual risk, are significant because of their frequencies in certain populations. A large number of other candidate genes have been proposed as risk factors for congenital thrombophilia.[30] However, most of these candidates have not undergone careful segregation or population studies to define their pathogenic role. In fact, some of the seemingly obvious candidates such as abnormalities in fibrinolysis do not appear to confer thrombotic risk.[31] These latter studies are, however, hampered by the low prevalence of most of these inherited abnormalities in the general population.

Reports demonstrate an increased risk for thrombosis in families with a second genetic abnormality.[32] Most reports have described a combination of FV-R506Q with abnormalities of PC, PS, or AT. These findings begin to shed light on the marked variability in clinical expression of these syndromes. The effect of more severe deficiencies has long been evident from the severely affected neonates with homozygous PC and PS deficiency. Apart from the well-defined homozygous cases, the risk and severity of thrombosis appear to vary with the type and number of underlying genetic abnormalities.[32-34]

The role of these congenital prothrombotic states in childhood thrombosis remains controversial. Despite meta-analyses suggesting that thrombophilia is a significant risk factor in childhood thrombosis, there are serious limitations to the published literature on which these meta-analyses are based.[35]

The reported incidence of congenital prothrombotic disorders in children with venous thrombosis varies from less than 1% to over 60%.[33,34,36-64] If one considers the deficiencies of AT, PC, and PS in addition to the factor V Leiden and prothrombin gene mutations, large family studies found negligible rates of thrombosis in children younger than 15 years.[65] A number of cohort studies have failed to identify AT deficiency in children with both arterial and venous thrombosis.[53,54,56,57] Those studies that reported higher frequencies of AT deficiency did not distinguish between acquired and inherited deficiency. In children with cancer and venous thrombosis, the reported incidences of thrombophilias are 3%.[52,57] The variability in incidence reported in all these studies reflects small sample sizes, variability in study design, differing definitions of prothrombotic disorders, and different patient selection criteria.[66] A prospective study of an unselected cohort of children with venous thrombosis found that with the exception of teenagers with spontaneous thrombosis, inherited thrombophilic markers did not contribute significantly to the pathogenesis of venous thrombosis in children.[67]

Screening for congenital prothrombotic disorders in children with venous thrombosis is of unproved benefit, regardless of the presence or absence of acquired risk factors. At this time, uniform screening of children with major illnesses, or those who require CVCs, for congenital prothrombotic disorders in order to provide prophylactic therapy cannot be recommended. The contribution of congenital prothrombotic disorders to venous thrombosis in pediatric patients remains to be clarified. Few children develop thrombosis due to a heterozygote congenital prothrombotic condition without also having an acquired risk factor.[51,68-76]

In summary, the data supporting inherited thrombophilia as a major factor in thrombosis in childhood are conflicting. In the PICU, it is likely that the dominant factors are clinical risk factors for thrombosis and that, if it contributes at all, thrombophilia may act as an additional hit in a multihit pathogenesis. However, there remains no evidence to support routine screening for thrombophilia, and there are certainly no data to support primary prophylaxis of children with inherited heterozygous thrombophilia. Further, there is no evidence that the presence or absence of thrombophilia changes acute treatment once a thrombosis is diagnosed. Given the inherent difficulties in interpreting at least the functional assays of protein levels in acutely sick children, there seems little role for thrombophilia testing in the PICU.

Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia (HIT) occurs in approximately 3% to 5% of adults exposed to UFH and is typically associated with a reduced platelet count, occurrence 5 to 10 days after heparin exposure, and an increased risk of thrombosis despite the thrombocytopenia. HIT is the result of a complex antigen-antibody interaction, and the most important therapeutic intervention once HIT is diagnosed is the immediate withdrawal of all heparinoid anticoagulants and substitution with nonheparinoid drugs until the risk of thrombosis is ameliorated.[77]

A number of case reports of pediatric HIT have described patients ranging in age from 3 months to 15 years.[15,78-82] UFH exposure in these cases ranged from low-dose exposure during heparin flushes used in maintaining patency of venous access devices, to supratherapeutic doses given during cardiopulmonary bypass and

hemodialysis. Studies specifically examining the frequency of HIT in children have varied in their reported results, likely related to differences in patient inclusion and laboratory techniques.[83-87] Reported rates vary from almost nonexistent in unselected heparinized children[86] to up to 2.3% in children in the PICU.[87] However, HIT appears to occur far less frequently in children than in adults, and the rationale for this is unclear.[86] Many patients in the neonatal intensive care unit/PICU who are exposed to UFH have multiple potential reasons for thrombocytopenia or thrombosis, and papers confirm that many positive HIT tests are in fact false positives.[88] Danaparoid, hirudin, and argatroban are alternatives to UFH in children with HIT[80-82,89-91]; however, these drugs have significant risks in children.[92] Until such time as the true clinical incidence of HIT in children is understood, the diagnostic tests have higher sensitivity and specificity, and there are safe and reliable alternatives to heparin therapy in acutely sick children, the diagnosis of HIT in children should be made with caution. Careful attention to the diagnostic criteria, exclusion of other causes, and rational use of test results are all required.

Clinical Features

The clinical symptoms and complications of venous thrombosis in children can be classified as acute or long term. The acute clinical symptoms include loss of CVC patency; swelling, pain, and discoloration of the related limb; swelling of the face and head with superior vena cava syndrome; and respiratory compromise with pulmonary embolus (PE). The long-term complications include prominent collateral circulation in the skin (face, back, chest, and neck as sequelae of upper venous thrombosis, and abdomen, pelvis, groin, and legs as sequelae of lower venous thrombosis), repeated loss of CVC patency, repeated requirement for CVC replacement, eventual loss of venous access, CVC-related sepsis, chylothorax, chylopericardium, recurrent thrombosis necessitating long-term anticoagulation and its risk of bleeding, and postthrombotic syndrome.

In adults, asymptomatic thromboses are not necessarily treated, and thrombosis experts argue that these thrombi are probably inconsequential. Symptomatic thrombi are treated to prevent embolism and extension. Asymptomatic thromboses in pediatric patients may carry significance for many reasons, namely the risk of sepsis, a potential source for a pulmonary embolus, and loss of access that may be life threatening for children requiring organ transplant. The relationship between VTE and infection remains complex, as each one appears to be risk factor for the other, and although it is appreciable that VTE can be a nidus for infection, having a bloodstream infection particularly with staphylococcus aureus is a potent stimulator for the development of VTE.[93] PE in children is frequently not diagnosed during life due to the subtle symptoms and the presence of other illnesses, but it can cause sudden respiratory compromise. However, PE most commonly results from CVC-related thrombosis and can cause death.[62] Additionally, in a child with a patent foramen ovale (or any cardiac right-to-left shunt) and venous thrombosis, stroke may occur as a result of the right-to-left intracardiac connection. Sudden death has been described in a few case reports from rupture of an intrathoracic collateral vessel thought to have resulted from CVC placement years earlier. Loss of venous access is a devastating complication of CVC-related thrombosis in children requiring vascular access for organ transplant, lifelong TPN, or dialysis. The exact rate of complications

from asymptomatic CVC-related deep vein thrombosis (DVT) in critically ill children is unknown. Despite the aforementioned theoretic reasons for why asymptomatic thromboses in children have raised concerns about the need for treatment, a study examining the acute complications of asymptomatic CVC-related DVT in critically ill children found no increase in complications.[83] This raises the question as to whether asymptomatic thromboses that are CVC related should be treated, and further research to answer this question is needed.

The clinical presentation of pulmonary embolus in children is often masked. In critically ill children, sudden cardiorespiratory deterioration can be due to a multitude of causes, and the difficulty in performing appropriate imaging to confirm the diagnosis of PE often means the diagnosis is either not considered or unable to be substantiated. Further, previously healthy children tend to tolerate large pulmonary embolus remarkably well, so often shortness of breath or dyspnea is transient, and the resolution of symptoms betrays the significance of the underlying pathology. Many children with substantial PE have no symptoms at all, until they demonstrate those of chronic venous hypertension or a subsequent further PE has fatal consequences. Clinical suspicion for PE must be high in all critically unwell children, especially those with central venous access devices in situ.

The clinical presentation of arterial thrombosis in children is often more straightforward, with cold, pale, pulseless limbs acutely related in time to the placement of an arterial catheter. However, other systemic arterial thrombosis, for example, emboli to abdominal organs, may present with vague and nondiscriminatory symptoms. Arterial thrombosis related to transplanted vessels may present as sudden graft loss.

Diagnosis

Venous Thrombosis

Little is known about the precision and accuracy of the noninvasive imaging techniques that are commonly used to make the diagnosis of venous thrombosis in neonates. There are few studies comparing currently used diagnostic tests. The low pulse pressure and small vessels in premature newborns can make ultrasound more difficult to interpret. Similarly, the presence of CVCs makes compressibility difficult to assess and, accordingly, greatly reduces the sensitivity of ultrasound. In neonates with umbilical vein catheters, Doppler ultrasound was shown to be poor compared to contrast venography in detecting asymptomatic thrombi.

The exception is renal vein thrombosis (RVT), where ultrasound is the radiographic test of choice because of its sensitivity in detecting an enlarged kidney, as distinct from the ability to detect intravascular thrombosis. Color Doppler ultrasound may demonstrate absent intrarenal and renal venous flow in the early stages of RVT. Magnetic resonance imaging (MRI) and computerized tomography (CT) have also been used for RVT, but they have no apparent advantages over ultrasound.

In summary, in neonates with suspected venous thrombosis, venography remains the gold standard where possible. Clinicians will often be forced to use a combination of clinical assessment and suboptimal imaging to make clinical decisions, because the gold standard is practically unachievable. This issue must be

factored into progressive decision making.

In older children, there are a few more data about diagnostic strategies. A well-designed substudy of the PAARKA investigation compared venography versus ultrasound for the diagnosis of asymptomatic upper venous system CVC-related venous thromboembolism. Ultrasound was demonstrated to have a sensitivity of 20% for intrathoracic thrombosis, yet it diagnosed jugular thrombi that were missed on venography.[94] The Linogram, Ultrasound, and Venogram (LUV) study compared linogram, ultrasound, and venography for the diagnosis of symptomatic upper venous system CVC-related thrombosis.[95] Most of the thrombi in this study were located in the jugular veins and diagnosed by ultrasound (80% sensitivity) but not venography.[96] Another study compared magnetic resonance venography (MRV) to ultrasound and linogram in 25 children with multiple CVC insertions who were suspected of having major central venous thrombosis.[96] Linogram consistently underestimated the extent of thrombosis. Ultrasound detected only 7 of 18 thromboses seen on MRV and underestimated the extent of 4 of the 7. In all cases, ultrasound identified jugular thrombosis but failed to identify more central thrombosis. Further, MRV identified a patent vein for reinsertion of CVC in 22 of 25 children. At operation, venous patency was confirmed in 20 patients (91%). There are no studies determining the sensitivity and specificity of diagnostic testing for lower venous system CVC-related thrombosis in children.

In summary, for children with suspected upper system thrombosis, a combination of ultrasound (jugular veins) and bilateral upper limb venography (subclavian and central veins) is recommended. The temptation to extend ultrasound imaging below the clavicles should be resisted. MRV may be a viable alternative to formal venography depending on local expertise. For children with suspected lower system thrombosis, ultrasound is a reasonable alternative for veins distal to the groin, based on adult experience. As in adults, serial ultrasound may be required to exclude thrombosis in specific circumstances. For more proximal veins, venography or MRV should be considered. Of importance, although there is considerable literature about the value of sensitive D-dimer assays in excluding DVT in adults, there are no such data in children. Furthermore, given the preceding medical and surgical therapies that most children with DVT have received, D-dimer is unlikely to be of use. At this time, D-dimer is not part of the recommended diagnostic strategy for venous thrombosis in children.

Pulmonary Embolus

There are no studies determining the sensitivity and specificity of diagnostic testing for PE in children. However, literature would support the conclusion that PE is significantly underdiagnosed in children, especially those in intensive care settings. A number of potential difficulties with interpreting ventilation/perfusion (V/Q) scans in children at risk from PE have been identified. This is particularly the case in children following specific cardiac surgeries such as Fontan surgery, where total pulmonary blood flow may not be assessed by isotope injected into an upper limb. The true impact of these difficulties on diagnostic accuracy remains to be determined. In addition, there are concerns about the safety of perfusion scanning in children with significant right-to-left cardiac shunts, as it is likely that significant amounts of macroaggregated albumin will lodge in the cerebral circulation, and the

impact of this factor is unknown.[97] Ventilation-perfusion scanning remains the recommended first-line investigation for PE in neonates and children. Pulmonary angiography remains the gold standard. Clinicians will frequently need to make a presumptive diagnosis based on clinical findings and the presence or absence of source thrombosis. CT pulmonary angiography may be an alternative, especially in the specific populations in whom V/Q scanning is more worrisome (eg, large right-to-left shunts), but CT may miss small peripheral pulmonary emboli. Further, repeated CT angiogram may cause significant radiation exposure to breast tissue in young female patients.[62]

Arterial Thrombosis

There is little specific information related to diagnostic strategies in neonates. Contrast angiography remains the gold standard. Peripheral arterial thrombosis is usually diagnosed clinically. Ultrasound remains unproved, although serial measurements may provide useful information. Aortic thrombosis, usually secondary to umbilical artery catheterization, requires radiologic diagnosis. Contrast angiography is rarely feasible in critically ill newborns. Noninvasive imaging techniques have not been validated. In fact, in one of the only comparative studies, ultrasound failed to visualize aortic thrombosis in four patients, three of whom had complete aortic obstruction by contrast angiography. Thus clinicians must often use clinical findings and suboptimal imaging to make clinical decisions.

In older children, many arterial thromboses are diagnosed on clinical grounds alone, for example, after femoral artery puncture. False negatives are reported using ultrasound to diagnose spontaneous femoral artery thrombosis in children. False-positive magnetic resonance angiography has been reported for chronic femoral artery obstruction when compared with formal angiography. In suspected peripheral artery thrombosis, clinicians should consider the possibility of intramural or external hematoma causing arterial compression as a differential diagnosis, and for peripheral arteries, ultrasound may be sufficiently sensitive to exclude this phenomenon.

Other important arterial thromboses are those that occur in the arterial supply to transplanted organs. For hepatic artery thrombosis after liver transplant, serial testing with pulsed Doppler combined with real-time ultrasound of the liver parenchyma has a sensitivity of approximately 70%. Both false-positive and false-negative results occur, such that angiography is usually required to confirm the diagnosis. Computerized tomography of the liver may be of aid in equivocal cases. Spiral CT has been shown to be sensitive and specific in adults. The value of MRI is yet to be fully determined.

Intracardiac Thrombosis

Three studies have specifically compared transthoracic echocardiography (TTE) to transesophageal echocardiography (TEE) in the diagnosis of intracardiac thrombosis following Fontan surgery.[98-100] Stumper and colleagues, in a cross-sectional survey of 18 patients, found three intracardiac thromboses using TEE, only one of which was detected by TTE. Fyfe and associates, in a similar study, found six thrombi in four pediatric patients using TEE, only one of which was detected by TTE. Balling and

coworkers performed a cross-sectional study of 52 patients after Fontan surgery. Seventeen patients (33%) had thromboses seen on TEE, only one of which was identified on TTE. Several other publications reported intracardiac thromboses diagnosed by TEE or angiography that were not detected using TTE. Thus transthoracic echocardiography is likely insufficient to exclude intracardiac thrombosis in children after Fontan surgery, although the studies published had a number of design flaws.

The validity of transthoracic echocardiography in other clinical situations is unknown, and clinicians should consider the local expertise, availability of TEE, and the clinical situation before determining the diagnostic approach in any individual child. Right atrial and intracardiac thromboses are most common in children with CVCs extending into the right atrium. Risk stratification based on clot size and mobility is suggested. For low-risk patients with clot size <2 cm, nonmobile and attached to atrial wall, removal of the CVC without anticoagulation may be appropriate.[101]

Management

Overall, the management of thrombosis in children is based around anticoagulation. There are a multitude of reasons why anticoagulation therapy in children is more difficult to manage than anticoagulation therapy in adults, and some of these reasons are listed in Table 92.2. The indications for surgical intervention or thrombolysis are few and far between. A limited drug arsenal exists in terms of drugs for which there is experience in children. No anticoagulants are formally approved for use in children, so all anticoagulants are used off label. In critically unwell children, there are often multiple relative or even absolute contraindications to anticoagulation, and the balance of risk versus benefit is difficult to ascertain due to the lack of well-designed studies. In general, anticoagulation is best managed by a pediatric hematologist experienced in thrombosis and anticoagulation, in consultation with the critical care team. At all times, the overall management of the child's underlying condition must be kept in perspective versus the management of an individual thrombosis.

TABLE 92.2

Factors That Increase the Complexity of Anticoagulant Therapy in Children Compared With Adults

Factor	Impact
Epidemiology of thrombosis	Increased proportion of sick children with multiple comorbidities
Developmental hemostasis	Affects response to therapeutic agents
Pharmacokinetic differences	Volume of distribution, binding, and clearance of drugs varies with age
Concurrent illnesses	Increased frequency of intercurrent infections (and hence medications) in children
Less diagnostic certainty	Requirement for general anesthetic to perform diagnostic studies impairs ability to investigate and monitor thrombosis in children
Limited vascular access	Delivery of intravenous therapy and monitoring of anticoagulant therapy more difficult
Drug formulations	All anticoagulants are “off label” in children and there are no specific pediatric preparations, making accurate dosing difficult
Dietary differences	Formula-fed versus breast-fed infants have vastly different responses to certain drugs (eg,

	vitamin K antagonists)
Compliance	Age significantly affects ability to understand and cooperate with therapy
Parental supervision	Children in dysfunctional families present special management issues not seen in adults

In terms of specific guidelines for managing thrombosis in children, the American College of Chest Physicians regularly publishes evidence-based guidelines, and the reader is referred to the most up-to-date version of these guidelines as the best overall guide to antithrombotic therapy in children.[15]

The most common drug used in critically unwell children is unfractionated heparin. Of all currently available anticoagulants, it is the only intravenous preparation with a short half-life and rapid onset and offset for which there is a known antidote. Low-molecular-weight heparins such as enoxaparin, tinzaparin, and dalteparin are all indicated for subcutaneous use in children. Although there are many situations in which low-molecular-weight heparins are advantageous, their long half-life and lack of reversibility with protamine usually make them poor anticoagulants for critically unwell children. Oral anticoagulation with coumarin derivatives such as warfarin is suitable for long-term anticoagulation, but the need for oral administration, slow onset of action, and long half-life make them unsuitable for acute anticoagulation of critically unwell children. A multitude of newer anticoagulants are available for use in adults, and their use in children has been reviewed.[92] To date, the outcome of these newer drugs when used in children has been poor. The lack of antidote for most of them is an important limitation when considering their use in critically ill children. Thus until further research identifies an alternative anticoagulant that has the advantageous properties of UFH, it will remain the anticoagulant of choice in PICUs.

Unfractionated Heparin in Children

UFH can be used as a first-line intervention to treat arterial and venous thromboses in infants and children. In addition, UFH also has numerous indications for primary thromboprophylaxis in infants and children, including cardiac angiography, artificial circuits (eg, cardiopulmonary bypass, hemodialysis, extracorporeal membrane oxygenation), arterial cannulation, and venoocclusive disease prevention during bone marrow transplantation. The short half-life of UFH makes it the ideal antithrombotic agent for use in critically ill children who are at greater risk of bleeding complications but who nonetheless require antithrombotic therapy.[102]

Unfractionated heparin is a complex glycosaminoglycan capable of binding to many circulating proteins as well as to the vascular endothelium.[103-105] The anticoagulant effect of therapeutic doses of UFH is largely limited to its interaction with antithrombin and tissue factor pathway inhibitor. Unfractionated heparin binding to AT occurs via a unique pentasaccharide sequence present in approximately one-third of UFH molecules.[105] The UFH:AT complex produces a thousandfold increase in AT inhibition of coagulation protein activity compared to AT alone.[106] Following intravenous administration of UFH, tissue factor pathway inhibitor (TFPI) release from the vascular endothelium increases in a dose- and concentration-dependent manner. [107] Unfractionated heparin is believed to increase the antithrombotic effect of TFPI by increasing its affinity for factor Xa by simultaneously binding to both proteins (Table 92.3).

TABLE 92.3

Factors in Children That Affect the Action of Unfractionated Heparin

UFH Factor	Age-Related Difference
UFH acts via AT-mediated catabolism of thrombin and factor Xa	Reduced levels of AT [3,4]
	Reduced capacity to generate thrombin[10,11]
	Age-related difference in anti-Xa/anti-IIa activity
UFH is bound to plasma proteins, which limits free active UFH	Alterations in plasma binding
Endothelial release of TFPI	Age-related differences in amount of TFPI release for same amount of UFH

UFH, unfractionated heparin.

The monitoring of UFH therapy in the PICU is a major problem. For many indications, there is no clear therapeutic range and certainly no clinical outcome data in pediatrics to support any particular therapeutic range. In addition, each of the monitoring tests available has significant limitations, particularly in children. Clearly, global measures of hemostasis such as the APTT will always be limited by confounding variables that affect results. Direct measurement of UFH's ability to inhibit specific coagulation proteins (eg, factor Xa), while producing definitive values, only represents one component of UFH's inhibitory effect on in vivo coagulation. Protamine titration has been viewed as the gold standard with respect to the measurement of UFH; however, the lack of automation renders protamine titration less clinically practical. A summary of the available tests for monitoring UFH and their shortcomings in pediatrics is presented in Table 92.4.

TABLE 92.4

Assays Used in the Monitoring of Unfractionated Heparin Therapy

Assay	Common Uses	Advantages	Disadvantages in Children
APTT F-Clot	Coagulation screening assay Therapeutic UFH monitoring	Low cost Easy to perform Widely available	Baseline APTT often prolonged in children Wide variability in reagent sensitivity to age-related differences Nonphysiologic measure of UFH effect No validation of therapeutic ranges in children
TCT F-Clot	Coagulation screening assay Therapeutic UFH monitoring (rarely)	Easy to perform	Patients previously exposed to topical thrombin may have antibodies causing prolongation of the clotting time Optimal concentration of thrombin used for the assay is unknown No validated reference range for UFH in children
ACT F-clot	CPB, extracorporeal circuits	Easy bedside whole blood test Extensive experience in most PICUs	Does not correlate with any specific measures of heparin activity Analyzer dependent
Anti-Xa F-Ch	Calibration of APTT reference ranges Therapeutic UFH monitoring	Direct measure of UFH inhibition of Xa Easy to perform	Not as widely available as APTT and costs significantly more Does not measure other mechanisms of UFH effect (eg, anti-IIa) and assumes constant ration of effect, which is not true in children Some kits have exogenous AT, others have dextran sulphate, both of which will introduce in vitro error in small children for different reasons
Protamine titration Q	Not used clinically Used by reference laboratories	Only assay that directly measures UFH concentration Low cost	Not widely available Automated methods have not been validated for management of therapeutic UFH and manual methods labor intensive

ACT, activated clotting time; *APTT*, activated partial thromboplastin time; *AT*, antithrombin; *F-Ch*, functional, chromogenic assay; *F-Clot*, Functional, clot-based assay; *Q*, quantitative assay; *TCT*, thrombin clotting time; *UFH*, unfractionated heparin.

The most important adverse effect from heparin therapy in children is bleeding.

One cohort study reported bleeding in 1.5% (95% CI, 0.0% to 8.3%) of children treated with UFH for DVT/PE. However, many children were treated with subtherapeutic doses of UFH (compared to the target APTT) in this study.[108] A single-center cohort study reported a major bleeding rate of 24% in children in PICUs receiving UFH therapy.[109] Further studies are required to determine the true frequency of UFH-induced bleeding in optimally treated children. There are only three case reports of pediatric UFH-induced osteoporosis. In two of these, the patient received concurrent steroid therapy. However, given the convincing relationship between UFH and osteoporosis in adults, clinicians should avoid long-term use of UFH in children when alternative anticoagulants are available. HIT was discussed previously in this chapter.

When considering bleeding as an adverse effect of UFH, clinicians frequently view this complication as a consequence of trying to manage the balance between bleeding and clotting in critically ill children. However, in reality, one of the most common reasons for heparin-associated bleeding is an accidental overdose of UFH. This often occurs in children who are receiving low-dose UFH flushing of vascular access devices, intended, for example, to be 50 units UFH/5 mL. Errors in vial selection and failure of bedside checking procedures result in 5000 units UFH/5 mL being injected, and in small infants this results in a massive overdose of UFH. Although reports of such events rarely occur in the medical literature, and in fact there are no specific reports of this outcome in the literature for more than 20 years, the popular press is littered with reports of medicolegal activity and deaths of children due to such errors. A Google search of heparin overdose in children will highlight many incidents, several with fatal outcomes. Fig. 92.3 summarizes the range of heparin preparations found in a typical PICU. It is not hard to see how such errors occur in busy units that operate 24 hours per day. Units should actively manage the choices of UFH preparations available to their staff to minimize the risk of confusion. Staff should be educated in the dangers of UFH and encouraged to be vigilant at all times when administering a drug that consistently ranks in hospital lists of the drugs most commonly involved in medication errors.

FIG. 92.3 Preparations of UFH commonly found on an Australian pediatric ward. Note the minimal differences in packaging, and the significant differences in UFH concentration, such that there is potential for a 100-fold overdose should a selection error be made.

Another adverse event from UFH is anaphylaxis, which in 2007–2008 accounted for more than 80 deaths due to an unintended contaminant introduced in the manufacturing process. Again, although there is almost nothing in the medical literature describing these events, the US Food and Drug Administration (FDA) released a number of warning statements, and one impact has been the move to make changes to the labeling of UFH. The potential for contamination of drug products made from biological sources will always be real. An important mechanism to minimize this risk is to ensure that children only receive UFH when the risks are clearly outweighed by the benefits. UFH has been described as being ubiquitous in PICUs, and clinicians should actively minimize unnecessary exposure.

In summary, anticoagulation in children in PICU is common, and UFH is the most common agent currently utilized. Although there remain many concerns about the potential adverse effects of UFH, there are currently no real alternative anticoagulant agents available for intravenous use in sick children. Many adverse events are related to dosing errors, and it is likely that PICUs can significantly improve the safety of UFH by developing systems to prevent medication errors. In addition, there is emerging evidence that our understanding of the pharmacokinetics of UFH in children and of the assays used to monitor UFH in children is far from ideal. Urgent research is required to improve the safety and utility of UFH in critically ill children.

Thromboprophylaxis in the Pediatric Intensive Care Unit

In critically ill adults, pharmacologic thromboprophylaxis is highly recommended due to its proved efficacy and safety in the prevention of DVT. It remains unclear if the same can be applied to the pediatric population. The increasing incidence of thromboembolism in the PICU patient has led several institutions to develop risk stratification protocols to target patients at the highest risk.[110,111] The most common risk factors continue to be the presence of CVC, cardiac disease, and infants <1 year.[19] There are various practices depending on the center, and currently between 0% and 50% of children receive thromboprophylaxis. A prospective study looking at pediatric trauma patients developed a risk stratification protocol and found a decrease by 65% in VTE with implementation of this protocol.[111] Of note, in this study of 76 patients determined to be at high risk for VTE, only 2 received pharmacologic thromboprophylaxis as per their protocol.

Routine thromboprophylaxis is unlikely to be of benefit in the PICU, as this area remains poorly studied and carries significant risk. The development of risk assessment tools and their effectiveness remains an area of research that is desperately needed. Nonpharmacologic thromboprophylaxis should be encouraged, which revolves around removing risk factors where possible, such as early mobilization and removal of CVC as soon as feasible.

Conclusions

Thromboembolic disease is now a major cause of mortality and morbidity in critically ill children, in the context of children having marked differences in the hemostatic system compared to adults, which appear to be age related. There remains much to be learned about the etiology and clinical presentations of thrombosis. Diagnostic strategies are mostly extrapolated from adult studies but are likely suboptimal. Similarly, management strategies and the use of anticoagulants in children for either treatment or primary prophylaxis are guided by minimal evidence, and there is a desperate need for further research. In the meantime, clinical decisions must be made, and for the time being these decisions require considerable consideration of the individual risk-benefit ratios for each patient.

CHAPTER 93

Transfusion Medicine in the Pediatric Intensive Care Unit

Jacques Lacroix, Marisa Tucci, Oliver Karam, Philip C. Spinella

PEARLS

- The decision to prescribe the transfusion of any blood product must be based on individualized indications and must take into account specific health problems.
- Acute severe anemia (hemoglobin concentration <5 g/dL) may increase the risk of death in critically ill patients.
- There is no evidence that a red cell transfusion improves outcomes in stable critically ill children if their hemoglobin concentration is >7 g/dL. A hemoglobin concentration higher than 7 g/dL may be required in unstable critically ill children and in pediatric intensive care patients with heart disease, particularly those with cyanotic heart disease, but the best threshold is unknown.
- Plasma can be useful to treat severe coagulopathy.
- Plasma should not be used as a volume expander.
- Platelets can be useful to treat bleeding caused by low platelet counts or platelet dysfunction.
- In pediatric intensive care units, most transfusion-related adverse events are linked to immunomediated effects of blood products rather than to transfusion-transmitted infectious diseases.

Red Blood Cells

Native red blood cells (RBCs) contain hemoglobin (Hb), which carries oxygen (O_2) to cells, thus allowing efficient adenosine triphosphate (ATP) production and ensuring cell survival. Because energy expenditure is high in critically ill patients, it would seem rational to maintain their Hb level in the normal range. Anemia is observed in 74% of critically ill children.[1] The transfusion of RBC units is the only effective way to rapidly increase the Hb level. However, the efficacy and safety of transfused RBCs

have been questioned. Infections transmitted by blood products were the most important concern in the 1980s. In the 1990s, noninfectious serious hazards of transfusion (NISHOT), like transfusion-related immune modulation (TRIM),[2] transfusion-related acute lung injury (TRALI), transfusion-associated circulatory overload (TACO),[3-5] and multiple organ dysfunction syndrome (MODS)[6-8] have become significant concerns.

This chapter discusses anemia and O_2 delivery (DO_2), reviews evidence on the effectiveness of RBC transfusion in the intensive care setting, discusses the recommendations found in guidelines on RBC transfusion in critically ill children, and reviews the most frequent transfusion reactions.

Red Blood Cell Transfusion: Why and Why Not

Anemia and O_2 Delivery

O_2 Delivery in the Critically Ill

Anemia decreases the capacity of blood to deliver O_2 because of lower Hb content. Systemic (global) DO_2 is dependent on cardiac output and the arterial concentration of O_2 (CaO_2): DO_2 = cardiac output (stroke volume × heart rate) × CaO_2. CaO_2 is defined by the formula:

$$CaO_2(\text{mL } O_2/\text{dL}) = \{(Hb \times SaO_2 \times 1.34) + (0.003 \times PaO_2)\} \qquad \textbf{Eq. 93.1}$$

Because systemic DO_2 is directly linked to Hb concentration, the most rapid and effective way of increasing DO_2 (within minutes) is by giving an RBC transfusion. This presumes that the Hb in a transfused unit of RBCs is functional and able to deliver O_2 to the tissues (see also Chapter 89). More modest augmentation in systemic DO_2 can be attained by increasing cardiac output or SaO_2.

An adequate O_2 delivery to cells does not imply necessarily that O_2 consumption (VO_2) is adequate and that cells produce enough energy. VO_2 depends on substrate availability and on metabolic demands; it can be amplified by increasing cellular O_2 extraction rate (O_2ER) or by increasing DO_2 if there is VO_2/DO_2 dependence.

The relationship between O_2 delivery and consumption is characterized by two phases: a directly linear relationship between VO_2 and DO_2 up to a “critical threshold” (often referred to as the critical DO_2) and a flat section above this threshold (Fig. 93.1). Below the threshold, VO_2 diminishes if DO_2 decreases. Above this threshold, a fall in DO_2 does not cause a drop in VO_2 because it is compensated by mechanisms like an increase in O_2ER; these mechanisms are limited though, which explains why there is a critical threshold of DO_2 under which O_2ER cannot increase any further, and below which VO_2 begins to fall.

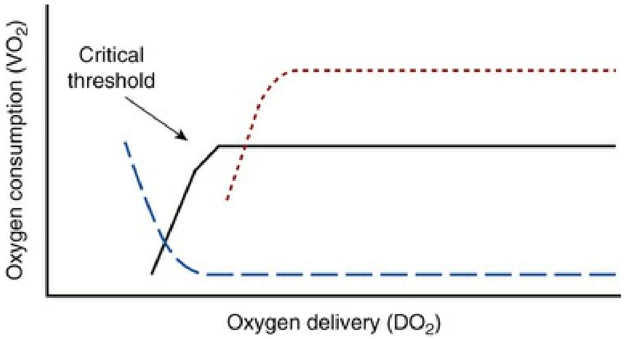

FIG. 93.1 This figure illustrates the relationship between oxygen delivery (DO_2) and O_2 consumption (VO_2) in normal patients *(black line)*, of DO_2 and blood lactate level in normal patients *(hatched blue line)*, and of DO_2 and VO_2 in septic critically ill patients *(red dotted line)*. Under the "critical threshold" marked by an arrow, VO_2 diminishes and blood lactate level increases if DO_2 decreases. Over this threshold, a fall in DO_2 does not cause a drop in VO_2 because it is compensated by an increase in O_2 extraction or an increased cardiac index. In critically ill patients, the VO_2 is frequently higher than normal. Then the level of the DO_2/VO_2 curve *(red dotted line)* is shifted upward; the critical threshold may also be shifted to the right, which may explain why pathologic O_2 supply dependence is reported in some critically ill patients.

The stress of critical illness increases metabolic rate and VO_2, which shifts the critical level of DO_2 to the right and upward. However, compensatory mechanisms are limited in anemic critically ill patients.

Adaptive Mechanisms With Anemia

Anemia significantly decreases blood O_2 carrying capacity. However, in the normal host, the amount of O_2 delivered to tissues exceeds resting O_2 requirements by a two-to-fourfold factor. While the Hb concentration is dropping, several adaptive processes maintain VO_2. These processes include (1) increased O_2ER; (2) increased heart rate and stroke volume, which increase cardiac output; (3) redistribution of blood flow from nonvital organs toward the heart and brain, at the expense of O_2 delivery to less important vascular beds, like the splanchnic vasculature; and (4) right shift of the oxy-Hb-dissociation curve, which decreases affinity between Hb and O_2, thereby increasing the amount of O_2 released to cells.

Increasing O_2ER is an important way to adapt to anemia. The upper range of normal O_2ER is 30%; O_2ER increases if O_2 requirements are not met. Higher O_2ER is frequently observed in severely ill patients, which translates into low $SmvO_2$ (mixed venous O_2 saturation and $ScvO_2$ (central venous O_2 saturation). When maximal O_2ER is attained and other adaptive mechanisms are overwhelmed, VO_2/DO_2 dependence appears and may result in O_2 debt, which is associated with mortality. O_2 requirements are increased in patients with sepsis and MODS. Impaired left ventricular function and abnormal regulation of their vascular tone can restrict DO_2 and disturb redistribution of regional blood flow. Moreover, the mitochondria of patients with severe sepsis and MODS are dysfunctional and cannot adequately

produce ATP.[9] A severe energy crisis may result (see also Chapter 80).

A number of host characteristics specific to children and infants may also impair their adaptive mechanisms. Although an increase in cardiac output generally compensates for anemia, this may not occur in the first few weeks of life due to lower myocardial compliance during this period and a significant impairment in diastolic filling, which limits stroke volume increase. In addition, an elevated resting heart rate in newborns also limits their ability to increase cardiac output. Greater energy requirements in young infants and children mostly attributable to growth imply a greater need for substrates including O_2. Issues affecting O_2 transport and release in children also include a higher proportion of fetal Hb during the first months of life, which caused a left shift of the oxy-Hb saturation curve, and a physiologic anemia.

O_2 Kinetics in the Critically Ill

Tissue hypoxia from low DO_2 may be due to low Hb concentration (anemic hypoxia), low cardiac output (stagnant hypoxia), or low Hb saturation (hypoxic hypoxia). A significant number of intensivists use RBC transfusion to increase DO_2 in critically ill children.[10] RBC transfusion indeed increases DO_2, but it does not always increase tissue VO_2 in ICU patients.[11] Several mechanisms may explain this outcome.[12] Mitochondrial dysfunction can impede O_2 utilization in critically ill patients.[9] Moreover, peripheral O_2 delivery is impaired in ICU patients, and there is some evidence that RBC transfusion may worsen that problem.[13]

Regulation by Red Blood Cells of DO_2 to Tissue

Although RBC transfusion certainly increases systemic DO_2 in the central circulation, this does not imply that regional O_2 delivery improves. There is indeed evidence that RBC transfusion may disturb local DO_2.[14] However, data on regional DO_2 are inconsistent, their clinical significance remains to be determined, and the underlying mechanisms, which may involve blood viscosity, microcirculatory flow, local DO_2, and cellular respiration, are not well characterized.

RBC transfusion increases blood viscosity, which can lead to microcirculatory stasis and impaired DO_2 to tissues.[15] No hard data indicate that blood viscosity is a clinically important problem unless the Hb level is above 20 g/dL.

Activation of white blood cells (WBCs) in packed RBC units and cytokine generation in the supernatant of transfused RBC units may also have a microcirculatory effect: Some cytokines can mediate vasoconstriction or thrombosis of small vessels and cause local ischemia. Most packed RBC units are now prestorage leukocyte reduced, which significantly decreases cytokine levels in the supernatant. The clinical impact of cytokines on regional DO_2 remains to be determined.

There is evidence that RBC transfusion can cause vasoconstriction of microvasculature via an interaction between intracellular Hb and uptake by RBCs of nitric oxide released by blood vessels. With local tissue hypoxia, Hb in the microvasculature releases nitric oxide and triggers local vasodilatation; conversely, if

there is sufficient O_2 in the microvasculature, Hb traps nitric oxide and causes vasoconstriction. This regulatory mechanism is almost immediately lost once RBCs are stored: It has been shown that in vitro exposure of blood vessels to RBC units stored 3 hours or more causes vasoconstriction.[16,17] The clinical significance of these observations is not clear; nonetheless they suggest that regional DO_2 can be disturbed by RBC transfusion.

Packed RBC units undergo several changes during storage, which are generally referred to as "storage lesion."[12,18] For example, the level of 2,3-DPG in stored RBCs decreases over time and can induce a left shift in the oxy-Hb dissociation curve, which impedes O_2 release to tissues even if systemic DO_2 is increased.[17] In addition, RBC deformability decreases after 2 or 3 weeks of storage, which may alter their capacity to pass through the capillary bed. Furthermore, hemolysis in older packed RBC units releases substantial amounts of free Hb ranging from 0.5 mg/dL in a 1-day-old RBC unit to 250 mg/dL in a 25-day-old unit.[19] Moreover, microparticles are released by RBC stored more than 2 or 3 weeks. Free intravascular Hb and microparticles have the ability to tightly bind nitric oxide and therefore cause vasoconstriction.[20]

Thus, although RBC transfusions certainly increase systemic DO_2, some available evidence suggests that impaired microcirculatory flow and O_2 availability can occur, which may have adverse effects on tissue oxygenation and cellular respiration.

Transfusion of Red Blood Cells: Indications (When)

A prospective cohort study involving 30 North American pediatric intensive care units (PICUs) reported that the proportion of patients who received at least one RBC transfusion while in the PICU ranged from 15% to 75%.[1]

RBC transfusions are clearly indicated for the treatment of hemorrhagic shock.[11] In such instances, the decision to prescribe RBC transfusions should be based on the physiologic state, the estimated amount of blood loss, and the risk of ongoing hemorrhage and not on the Hb concentration.

RBC transfusion is more questionable if there is no clinically significant hemorrhage or bleeding. Pediatric intensivists have stated in two surveys that their decision to prescribe an RBC transfusion would be based on reasons such as a low DO_2 or VO_2, cardiovascular insufficiency, respiratory failure, or use of certain specific technologies such as extracorporeal membrane oxygenation (ECMO), hemodialysis, hemofiltration, plasmapheresis, or exchange transfusion; nonetheless the most frequent reason to transfuse RBCs was reported to be a low Hb concentration.[1,10] The Hb level that should prompt a pediatric intensivist to prescribe an RBC transfusion remains a matter of debate, but there is some evidence in the medical literature that can guide practitioners.

Anemia

Severe anemia is associated with a higher risk of mortality. Carson and associates combined the data of two studies involving bloodless surgery in adults; the

unadjusted mortality rate was 0.9% when the nadir Hb level was ≥7 g/dL, 9% if it was between 5 and 7 g/dL, 29.8% if it was between 4 and 5 g/dL, and 41% if it was <4 g/dL[21-23] Clearly, the risk of mortality augments when the Hb level falls below 5 g/dl. It is less obvious when to transfuse if the nadir Hb level is between 5 and 7 g/dL. It is important to recognize that the relationship between anemia and outcomes does not mean that transfusion to treat anemia will necessarily improve outcomes.

There are fewer data on the relationship between anemia and adverse outcome in children. Lackritz and colleagues[24] followed 2433 anemic African children among whom 20% received RBCs in the form of a whole blood transfusion; whole blood transfusion seemed beneficial if the Hb level was below 4.7 g/dL and if the patient presented some respiratory distress. Given these data, local guidelines were implemented recommending that RBCs should be transfused to hospitalized children if their Hb level was <5 g/dL. Lackritz and colleagues[25] subsequently enrolled 303 children with a Hb level <5 g/dL; 116 (38%) did not receive a transfusion, mostly because blood products units were not available. Each child with severe anemia was matched with the next child hospitalized with a Hb >5 g/dL. Death rates were 19.5% in 303 patients with a Hb >5 g/dL who were not transfused, 21.4% in 187 patients with a Hb <5 g/dL who were transfused, and 41.4% in 116 patients with a Hb <5 g/dL who were not transfused. English and coworkers[26] completed a prospective cohort study of 1269 children with malaria hospitalized in Kenya; blood transfusion seemed to decrease mortality if anemia was severe (Hb level <4 g/dL) or if a Hb level <5 g/dL was associated with dyspnea. These studies suggest that the risk of mortality increases significantly in children ill enough to require hospitalization if their Hb concentration is lower than 5 g/dL, particularly if respiratory symptoms are present.

Evidence on Red Blood Cell Transfusion

Four case series assessed hemodynamic parameters before and after a 10- to 20-mL/kg RBC transfusion; those studied were children with septic shock, postoperative pediatric cardiac surgery patients, and children with cyanotic heart disease undergoing elective cardiac catheterization.[27-30] These articles reported a greater systemic DO_2 after transfusion, but only one study reported an increase in calculated VO_2.[27] RBC transfusion increases systemic DO_2, but it does not increase VO_2 in many instances.

Two randomized controlled trials evaluated RBC transfusion strategies in children. The first trial was performed in 106 African children with malaria crisis (hematocrit: 12% to 17%). Whole blood transfusion did not improve the mortality rate (1/53 versus 2/53) in patients without respiratory or cardiovascular compromise.[31] In the transfusion requirement in PICU (TRIPICU) study, a randomized controlled trial involving 637 stable critically ill children with Hb level <9.5 g/dL, 320 patients were allocated to an RBC transfusion threshold of 7 g/dL of Hb (restrictive group) and 317 to a threshold of 9.5 g/dL (liberal group). A statistically significant noninferiority was found: 38 and 39 patients, respectively, developed new or progressive MODS, and there were 14 deaths in both strategy groups within 28 days postrandomization. The conclusion was that a restrictive strategy is as safe as a liberal strategy in stable critically ill children. Moreover, given that 174 patients (54%) in the restrictive group received no RBC transfusion

compared to 7 (2%) in the liberal group ($p < 0.0001$) and that patients in the restrictive group received 54% fewer RBC transfusions, the findings supported adopting a restrictive transfusion strategy for stabilized critically ill children.[32] Three subgroup analyses, respectively, on patients with sepsis,[33] on postoperative cardiac patients,[34] and on noncardiac surgery cases[35] showed trends identical to those reported in the original TRIPICU study.

Red Blood Cell Transfusion: Current Recommendations

Noncardiac Patients

RBC transfusion in PICU is associated not only with a low Hb level (multivariate odds ratio if Hb <7 g/dL: 61.3; 95% confidence interval [CI]: 27.75, 134.7) but also with congenital heart disease (3.61; 1.99, 6.55), age <12 months (2.43; 1.19, 4.96), higher severity of illness (daily PELOD score >20: 6.33; 1.72, 23.25), and presence of some organ dysfunctions (cardiovascular, hematologic, neurologic, or hepatic).[36] In a cohort study,[1] pediatric intensivists declared that they might consider prescribing an RBC transfusion based on the following markers: Hb concentration, low SaO_2, low PaO_2, low cardiac output (poor DO_2), high blood lactate level, low central venous ($ScvO_2$) or mixed venous saturation of O_2 ($SmvO_2$), poor VO_2, high severity of illness, active bleeding, and emergency surgery. However, how these determinants of RBC transfusion interacted with each other was unclear.

In the TRIPICU study, 234 and 246 patients with respiratory dysfunction were enrolled in the restrictive and liberal group (threshold Hb for RBC transfusion: 7 and 9.5 g/dL, respectively).[6] The number of cases of new/progressive MODS was similar (33 and 35), respectively. Duration of mechanical ventilation was also comparable in these 480 patients (6.4 ± 6 versus 6.3 ± 5.3 days; absolute risk difference: –0.16; 95% CI: –1.2, 0.9, $p = 0.75$), including 73 with an acute lung injury (ALI) (7.2 ± 6.5 versus 7.1 ± 6.2 days; absolute risk difference: –0.12; 95% CI: –3.1, 2.9, $p = 0.94$) and 48 with an acute respiratory distress syndrome (ARDS) (10.5 ± 9.2 versus 8.5 ± 7.2 days; absolute risk difference: –2; 95% CI: –6.8, 2.8, $p = 0.40$). Thus targeting higher Hb thresholds does not improve outcome in stable critically ill children with respiratory problems if their Hb level is >7 g/dL.

Although many physicians believe that a higher Hb level is required in severely ill septic patients, there is little evidence to support this belief. The outcome of 137 septic children (34 in septic shock, 31 with severe sepsis) allocated in the TRIPICU study to a restrictive or a liberal transfusion strategy was similar with 13/69 versus 13/68, respectively, developing new/progressive MODS (absolute risk difference: 0.3%; 95% CI: –12%, +14%).[37] Holst and colleagues[38] randomized 1005 adults with septic shock to receive an RBC transfusion only if their Hb level fell below 7 or 9 g/dL. Some of these patients were not hemodynamically stable. The 90-day mortality was similar (43% versus 45%; relative risk: 0.94; 95% CI: 0.78, 1.09; $p = 0.44$). Thus a threshold Hb of 7 g/dL can probably be safely applied in critically ill children with sepsis.

Guidelines from many organizations emphasize that the decision to administer RBC should not be based solely on Hb levels but should involve sound clinical judgment.[39,40] Goal-directed transfusion therapy is also frequently advocated.[41,42] Although it is theoretically rational to base the decision to transfuse RBCs on

physiologic need, it is still a matter of debate what parameters best determine that need. It has been suggested that an RBC transfusion is indicated for patients with symptomatic anemia, but most critically ill children are unable to report these symptoms. Some have suggested that systemic markers of oxygenation deficit (eg, systemic VO_2, VO_2/DO_2 dependence, blood lactate level, $ScvO_2$ or $SmvO_2$) or O_2ER, might be more useful.[43] Others have proposed that parameters reflecting regional oxygenation deficit, such as brain tissue O_2 pressure ($PbtO_2$),[44] gastric tonometry,[45] tissue O_2 saturation (StO_2) measured by near-infrared spectroscopy (NIRS),[14] or digital O_2 extraction rate measured by noninvasive devices, may be more reliable. Actually, it is presently not known which markers are best suited for this purpose and what cutoff values should be used to determine the need for RBC transfusion. The concept of goal-directed transfusion therapy is laudable, but it is presently vaguely defined and not supported by hard data. Specific recommendations for goal-directed transfusion therapy remain undetermined at the present time.[46]

In practice, a low Hb concentration remains the most frequent and the primary justification for pediatric intensivists to prescribe an RBC transfusion.[1] Therefore, it makes sense that the Hb concentration be the first parameter assessed when an RBC transfusion is considered. Given the available evidence, critically ill children should receive an RBC transfusion if their Hb level is below 5 g/dL. In stable patients, including septic patients,[37] patients having undergone noncardiac surgery,[35] severely burned children[47] and trauma patients,[48] it is suggested to consider RBC transfusion if the Hb concentration is <7 g/dL, but a transfusion is not recommended if the Hb concentration is above this level. However, determinants other than the Hb concentration must be considered including age, severity of illness, or evidence of organ dysfunction or O_2 dependency, such as elevated blood lactate level or low $ScvO_2$. For example, it would seem appropriate to consider a higher threshold and a more aggressive RBC transfusion strategy in unstable patients for whom the optimal and safe lower limit of the transfusion threshold has not been established. Moreover, any recommendations made must also factor in specific considerations for disorders like sickle cell disease[49] and cardiac conditions.

Cardiac Patients

Critically ill children with cardiac disease receive more RBC transfusions than other PICU patients.[36] There is no strong evidence that indicates this strategy improves outcomes.

Few clinical studies have addressed RBC transfusion in cyanotic heart disease. Experience with bloodless cardiac surgery for congenital heart disease in children whose families refuse transfusion seems to suggest that a lower Hb level may be well tolerated. This theory is supported by a randomized controlled trial involving 59 children undergoing bidirectional Glenn or Fontan procedures in which patients were allocated to either a restrictive or a liberal transfusion strategy (respective threshold: Hb concentration of 9 and 12 g/dL). The mean postoperative Hb was 11.1 ± 13 versus 13.9 ± 0.5 g/dL, and the mean number of RBC transfusions was 0.47 ± 0.6 versus 2.03 ± 1.2 per patient in the restrictive and liberal groups, respectively. No difference was noted with regard to surrogate outcomes such as peak blood lactate level (3 ± 1.5 versus 3.1 ± 1.3 mmol/L), ventilator support, duration of vasoactive agent administration, ICU or hospital length of stay, or survival.[50] More data are

required before a restrictive transfusion strategy can be safely implemented in patients with cyanotic heart disease.

On the other hand, there is some evidence that using a 7-g/dL threshold is safe in the postoperative care of noncyanotic congenital heart disease in stabilized patients older than 28 days. Willems and associates[34] analyzed a subgroup of 125 postoperative cardiac patients enrolled in the TRIPICU study after a cardiac surgery. No significant difference in the incidence of new or progressive MODS (12.7% versus 6.5%; $p = 0.36$), PICU length of stay (7 ± 5 versus 7.4 ± 6.4 days), or 28-day mortality (2 versus 2 deaths) was found between the restrictive and liberal groups. Another randomized controlled trial compared outcome in pediatric cardiac surgery patients aged more than 6 weeks allocated to receive an RBC transfusion if their Hb level dropped below 8 g/dL (restrictive) or 10.8 g/dL (liberal group).[51] Patients with cyanotic cardiac disease were excluded. Randomization occurred before surgery; the research protocol with respect to RBC transfusion was initiated in the operating room and maintained up to PICU discharge. In the 107 patients enrolled and retained for analysis, duration of mechanical ventilation, PICU length of stay, and the incidence of adverse events were similar in both groups, whereas hospital length of stay was shorter in the restrictive group (median: 8; [interquartile range: 7–11] versus 9 [7–14] days, $p = 0.063$). The British Society of Haematology[39] supports the acceptance of a postoperative Hb level of 7 g/dL in children when there is good postoperative cardiac function in the absence of persisting cyanotic heart disease. The Society of Thoracic Surgeons makes a similar recommendation for all cardiac surgery patients.[52] The data reported by Willems and associates[34] and de Gast-Bakker[51] support these recommendations.

Data in adults suggest that RBC transfusions may be detrimental in patients with cardiac conditions.[53] RBC transfusions must be used cautiously in children with cardiac disease. Given the currently available evidence, an Hb level of 7 g/dL can be considered safe for hemodynamically stable children older than 28 days who have noncyanotic heart disease and a level of 9 g/dL for children with cyanotic heart disease.[6,50] Further studies are needed to better characterize appropriate determinants for RBC transfusion in critically ill children with heart disease.

Prevention of Anemia and of Red Blood Cell Transfusion

Bloodless medicine is a popular concept; it refers to all the strategies that can be used to provide medical care without allogeneic RBC transfusion, including blood conservation. Many strategies can prevent or significantly decrease the number of RBC transfusions and exposure to transfusion. Adopting a restrictive RBC transfusion strategy in stable critically ill children is one of them; other strategies could include raising the Hb concentration before elective surgery, using blood products only when necessary, limiting blood loss, and administering the patient's own blood.

Bloodless medicine begins before surgery, when applicable. In the preoperative period, the use of erythropoietin and iron supplementation can be considered to optimize the preoperative Hb level, collection of autologous donations can take place to minimize or prevent allogeneic transfusion, medications that increase the risk of bleeding should be avoided, including herbal medicine (garlic, ginseng, ginger,

etc[42]), and optimal control of any existing coagulation disorders should be attained just prior to surgery.

During surgery, maximal attention should be given limiting blood loss[54] and ensuring good hemostasis and rapid control of any bleeding. In some instances, desmopressin, fibrin sealants, or antifibrinolytic agents such as aprotinin or tranexamic acid may be used to stop a hemorrhage. Recombinant activated factor VII (rFVIIa) is advocated by some practitioners, but it is associated with a significant risk of thrombosis; the cost-benefit ratio of rFVIIa in children is not well evaluated, and its use should be limited to situations involving uncontrolled life-threatening bleeding. Prothrombin complex and fibrinogen concentrates are also potential agents that can improve hemostasis in children with significant bleeding, but the appropriate indications for these agents and their safety profile in children are not well established. The safety and cost-effectiveness of intraoperative blood conservation strategies like normovolemic hemodilution, autologous blood cell salvage modalities, intraoperative autotransfusion, and deliberate hypotension remain to be determined.

Postoperative and ICU management of anemia and bleeding are also important. A restrictive transfusion strategy is in line with the concept of "permissive anemia" supported by the British Committee for Standards in Haematology Transfusion Task Force.[39] A prospective study reported that 73% of blood loss in the PICU is attributable to blood draws.[1] The number and frequency of blood tests must be limited, and the amount of blood collected reduced. Many devices can help to minimize blood loss, including the use of loop sampling, pediatric blood collection tubes, microanalysis techniques requiring small volumes of blood, and in-line measurement of parameters like blood gases and Hb concentration.

Erythropoietin response to anemia is blunted and poorer than expected in critically ill patients.[55] In spite of this response, erythropoietin can prevent anemia in critically ill adults,[56] in low-birth-weight preterm infants,[57] and in the postoperative care of neonates.[58] In critically ill children, there are no data to support the use of erythropoietin as a preventive measure because most RBC transfusions are administered within 2 or 3 days after PICU admission,[1,36,59] a period of time too short to allow for a response to erythropoietin, which generally occurs after several days. The standard use of erythropoietin is presently not recommended in the PICU.

Iron supplementation is also not indicated. In critically ill patients, it had no discernible effect on iron-deficient erythropoiesis, Hb concentration, and RBC transfusion requirement,[60] and it can even be harmful.[61]

Conclusion

RBC transfusion should be administered only if the anticipated benefits outweigh the potential risks. A threshold Hb concentration of 7 g/dL is adequate in most stable critically ill children.[6,46] The optimal Hb concentration or transfusion threshold above which the benefits outweigh the risks and costs remains to be determined in unstable patients and in patients with congenital heart disease.

Types of Packed Red Blood Cell Products

Standard Red Blood Cell Products

Packed Red Blood Cell Units

Storage of RBC units is made possible by refrigeration at about 4°C and by storage in preservative anticoagulant solutions that contain dextrose, sodium citrate, citric acid, and sodium diphosphate. RBCs use dextrose and phosphate to generate ATP, which is essential for their survival. Citrate blocks coagulation by chelating calcium; it is also metabolized to bicarbonate, which stabilizes the stored RBC unit pH above 6.4. RBCs in CPDA–1 (citrate-phosphate-dextrose-adenine) solution can be stored up to 35 days because the level of ATP is normal after 21 days of storage and is about 50% after 35 days. Packed RBC units are prepared by removing 200 to 250 mL of plasma from one unit of whole blood after centrifugation. To support the nutrient needs of RBCs after plasma is removed, additive solutions were developed, such as AS–1 (Adsol), AS–3 (Nutricel), and AS–5 (Optisol), and saline-adenine-glucose (SAG) or SAG-mannitol (SAGM)[62]; these additive solutions further decrease RBC lysis and allow for storage up to 42 days.

The volume of a CPDA–1 unit is about 250 mL, including 63 mL of preservative solution; it must be diluted with 75 mL of NaCl 0.9% before transfusion (final volume: 325 mL). The volume of an AS–3 unit is about 350 mL, and the volume of a SAGM unit is about 300 mL; both include approximately 100 mL of preservative solution and do not require any dilution.

Whole Blood

The use of whole blood has been advocated mostly for first-line therapy in hemorrhagic shock, as it contains RBCs, coagulation factors, and platelets.[63] However, it is generally not available. Approximately 15% of children's hospitals in the United States provide whole blood to children, predominantly for cardiac surgery, liver transplantation, and massive transfusion protocols. Some also uses whole blood units for neonatal exchange transfusions.[64] Whole blood is stored at 2° to 6°C for up to at least 21 days based on the storage solution. Barriers to whole blood availability have been based on the concepts that the platelets in whole blood will not be functional when stored at 2° to 6°C, whole blood cannot be leukocyte-reduced without removing platelets, and it must be ABO specific when transfused. These concepts have been challenged.[65,66] Platelets actually have increased hemostatic function when stored at 2° to 6°C compared to 20° to 24°C.[67,68] Function has been classically defined as circulation time, which may not be an appropriate measure of function in a patient with severe bleeding. Interestingly, two randomized controlled trials in humans have indicated that there is less blood loss or improved functional hemostatic measures for platelet-containing blood products stored at 2° to 6°C compared to 20° to 24°C.[69] Platelet-sparing leukoreduction filters are now available for whole blood units and in clinical use at children's hospitals. Lastly, when data from the UK Serious Hazards of Transfusion (SHOT) database were analyzed, it was inferred there is less risk of severe hemolytic reactions when group O whole blood is transfused compared to the use of ABO type specific whole blood.[62]

The use of whole blood is very controversial and it should only be considered for patients with hemorrhagic shock. Whole blood is not recommended in normovolemic patients because it can cause cardiac overload. The volume of a

typical whole blood unit is about 450 mL.

Other Types of Red Blood Cell Units

Many other types of RBC units are available: leukocyte-reduced, washed, irradiated, cytomegalovirus (CMV) negative, autologous, and directed.

Leukocyte-Reduced Red Blood Cell Units

Packed RBC units contain some nonviable platelets, small amounts of coagulation factors, and WBCs, which can release pro- and antiinflammatory mediators during storage. Prestorage leukocyte reduction is a standard procedure for all blood components in many countries, like Australia, Canada, and the United Kingdom; it can decrease the number of WBCs in packed RBC units from 1×10^9 to less 1×10^6 per product, the concentration of cytokines in the supernatant, as well as some T-cell–regulated immunomodulation.[70] In 2005 88% of packed RBC units given in US PICUs were leukocyte-reduced at collection.[1] Transmission of intracellular viruses like CMV and herpes is less frequent if there are fewer WBCs.

Washed Red Blood Cell Units

RBCs can be washed with sterile saline; the process removes not only 98% of plasma but also up to 20% of RBCs. RBC washing increases the hematocrit to 0.8, but the procedure takes up to 2 hours; thus it is impossible to use washed packed RBC units on an emergency basis unless they are prepared in advance. Washed units must be used within 24 hours after processing. Multiple wash cycles are required. The procedure may not completely remove all proteins and therefore does not prevent hypersensitivity reactions (eg, hypersensitivity to IgA). The overall volume of a washed RBC unit is significantly decreased (about 200 mL rather than 350 mL for an AS–3 RBC unit), making them sometimes useful to limit the volume administered in some patients. Washed RBC units should not be considered leukocyte-reduced.

A randomized controlled trial that included 161 children reported that washing RBC transfused in cardiac PICU patients reduces postoperative inflammation and number of transfusions.[71] A randomized trial of washed RBC and platelet transfusions in 43 adults with acute leukemia reported similar trends.[72] However, the washing process is not without consequences; for example, it increases hemolysis and decreases 2,3-DPG content.[73] Further studies are required before washing of all RBC units can be recommended for PICU patients.

Washed RBC units can be considered for patients with severe, recurrent allergic reactions to blood, patients with an anti-IgA deficiency, and some patients with a high risk or circulatory overload.

Irradiated Red Blood Cell Units

Some WBCs remain in RBC and platelets units, even in prestorage leukocyte-reduced units. The objective of irradiation is to induce enough DNA damage to prevent leukocyte proliferation.[74] Irradiation destroys the ability of transfused lymphocytes to divide and therefore to respond to host foreign antigens, thereby decreasing the risk of developing transfusion-associated graft-versus-host (TAGVH) disease in susceptible recipients. However, irradiation is not without drawbacks. For

example, it can damage the RBC membrane causing the release of significant amounts of free Hb and potassium. Moreover, the shelf life of irradiated RBC units is reduced from 42 to 28 days.[75]

Irradiated RBCs are indicated for all children with congenital or acquired cellular immune deficiency (eg, allogeneic stem cell transplant recipients, certain hematologic malignancies, myeloablative chemotherapy recipients) to prevent TAGVH disease. Because di George syndrome is not rare among infants with congenital heart disease undergoing cardiac surgery, these patients should receive irradiated units. Irradiation is also indicated in patients receiving directed donation from family members. Irradiation is not mandatory for patients with most solid tumors, routine immunosuppressive therapy (corticosteroids) solid organ transplantation, nonmyeloablative chemotherapy recipients, or humoral immunodeficiency.

Cytomegalovirus-Negative Red Blood Cell Units

RBC transfusion can transmit CMV infection. A large proportion (30% to 70%) of blood donors are CMV positive. Although it would be ideal to administer only CMV-negative RBC units to CMV-negative patients, the high prevalence of CMV infection among donors does not permit this. Nevertheless, prestorage leukocyte reduction of blood products decreases transmission of CMV to 1% to 2% (similar to the rate of infection following the transfusion of CMV-negative units) compared to standard products for which transmission is 13% to 37%.

Administration of a CMV-positive RBC unit is generally not an issue for immunocompetent patients. Established indications for CMV-negative units include CMV-negative recipients of organ or bone marrow transplants from CMV-negative donors, CMV-negative bone marrow transplant recipients, and intrauterine transfusions. Less well-established indications include CMV-negative patients who are potential candidates for autologous or allogeneic bone marrow transplant, CMV-negative patients undergoing splenectomy, potential seronegative donors for bone marrow transplant, and CMV-negative patients with HIV.

Directed Red Blood Cell Units

Directed blood is donated by family members or friends. Parents frequently believe that giving their own blood decreases the risks of transfusion, which, in practice, is not the case. A small increase of transfusion-transmitted infectious diseases has been reported.[76] Moreover, the risk of contracting a TAGVH is increased even in immunocompetent patients. Regardless, directed blood donation remains popular. Good clinical studies to better estimate the risk-benefit ratio of this practice are warranted. All directed RBC units must be irradiated pretransfusion.

Autologous Red Blood Cell Units

Older healthy children can give their own blood a few weeks before elective surgery. It is frequently believed that autologous RBC units are free of risk, which is untrue. These units are usually quite old by the time transfusion is required, which raises concerns with respect to RBC unit length of storage. Moreover, autologous RBC units are not leukocyte-reduced, at least in Canada. The risk-benefit ratio of autologous RBC units remains to be determined.

Red Blood Cell Substitutes and Other Alternatives to Red Blood Cell Transfusion

Hb-based O_2 carrier solutions (semisynthetic or synthetic preparations of Hb) and perfluorocarbon derivatives can carry O_2.[77] Both were developed as alternatives to RBCs, but there are serious concerns about their safety and usefulness. None can be recommended presently.

Transfusion of Red Blood Cells: How

RBC transfusion is the best way to rapidly increase the Hb concentration. Once a practitioner decides an RBC transfusion is warranted, several issues need to be decided including the type of RBC unit (discussed previously), the blood type, the volume necessary, how the unit must be perfused, and what monitoring is required.

Blood Types

Table 93.1 describes the compatibility of different blood products. A complete cross-match is mandatory before any transfusion is given, with few exceptions. Transfusion of group O Rh-negative RBC or group AB Rh-positive plasma can be life saving, but this must be reserved for severe and acute situations. It takes 15 to 20 minutes to type a patient for ABO and Rh. If there are no RBC antibodies, fully compatible blood or immediate spin cross-match may be issued quickly. In the case of RBC antibodies or other anomalies, a full serologic cross-match is required, which is lengthier. The risk of severe reaction to typed, but not cross-matched blood RBC units, is about 1/1000 if the patient has never received a transfusion; the risk is decreased 10-fold if a cross-match is done. It is recommended that similar units be used until patient recovery if a patient receives more than 20% of his or her blood volume with non–cross-matched packed RBC units. However, this practice is a little outdated, as there is little plasma in AS–3 and SAGM RBC units. If anti-A/B antibodies are detected on blood typing, then antigen-negative blood should be provided; otherwise ABO-identical units should be used when available. Repeat verification that the correct blood unit has been delivered to a given patient is essential because blood mismatch is the most important cause of severe transfusion reaction.

TABLE 93.1

Compatibility of Blood Products

Blood Product	Receiver	Donor
Packed RBC unit and whole blood	A	A, O
	B	B, O
	O	O
	AB	AB, A, B, O
	Rh^+	Rh^+ or Rh^-
	Rh^-	Rh^-
Plasma or platelets	A	A, AB
	B	B, AB
	O	O, A, B, AB
	AB	AB
Platelets	Rh^+	Rh^+ or Rh^-
	Rh^-	Rh^- or Rh^+[a]

[a]Give an anti-D vaccine (WinRho SDF) if the receiver is Rh^- and the platelet concentrate is Rh^+.

RBC, red blood cells.

For high-risk elective procedures, type and cross-matching done prior to any bleeding allows for compatible RBC units to be reserved. If an unforeseen emergency transfusion is required for an actively bleeding patient, it is impossible to deliver RBC units that are typed and cross-matched within a reasonable time frame and group O Rh-negative RBC units must be administered (some hospitals outside the United States also deliver O Rh-positive RBC units for men and for women after menopause, but this is not a common practice). Ordering a transfusion stat means transfusion is required within a few minutes; this is not indicated unless the patient is actively bleeding.

Volume and Number of Red Blood Cell Units

Prescribing the right volume of packed RBC units is important, as this prevents cardiac overload and limits exposure to several donors. An easy albeit simplistic rule of thumb exists that suggests administration of 10 mL/kg of packed RBC units increases the Hb level by 2 to 3 g/dL. If the Hb concentration is stable in a patient who is not actively bleeding, it is better to calculate the difference between the Hb concentration observed before transfusion and the targeted Hb level using the following formula:

$$\text{Volume (mL)} = [(\text{Hb}_{\text{targeted}} - \text{Hb}_{\text{observed}}) \times \text{blood volume}]/[\text{Hb}_{\text{RBC unit}}] \qquad \textbf{Eq. 93.2}$$

where $\text{Hb}_{\text{targeted}}$ is the Hb concentration targeted post transfusion (for example, 10 g/dL), where $\text{Hb}_{\text{observed}}$ is the most recently measured Hb concentration (g/dL), and where $\text{Hb}_{\text{RBC unit}}$ is the average Hb concentration in the packed RBC units (g/dL) delivered by the blood bank. Hb concentration in RBC units may vary depending on the center and the preservative solution. For example, the hematocrit of RBC units with AS–3 (Nutricel) is approximately 0.55, and $\text{Hb}_{\text{RBC unit}}$ concentration is about 19.5 g/dL (range: 18 to 21 g/dL); the hematocrit of CPDA–1 is 0.75 to 0.65, and the $\text{Hb}_{\text{RBC unit}}$ is about 25 g/dL. The blood volume can be calculated according to the following formula:

$$\text{Total body blood volume} = \text{weight} \times \text{blood volume} \qquad \textbf{Eq. 93.3}$$

where weight is expressed in kg and blood volume in liter/kg (0.08 L/kg for a less than 2-year-old child, 0.07 L/kg for 2 to 14 years of age). For example, if the $\text{Hb}_{\text{observed}}$ in a 2-week-old 3-kg baby is 6.5 g/dL, the baby's blood volume is 0.24 L (0.08 L/kg × 3 kg), and the $\text{Hb}_{\text{RBC unit}}$ is 19.5 g/dL (AS–3), and if the physician targets a Hb concentration ($\text{Hb}_{\text{targeted}}$) of 10 g/dL, the volume of RBC unit to be transfused would be as follows:

$$\text{Volume} = \{(10\ \text{g/dL} - 6.5\ \text{g/dL}) \times 0.24\ \text{L}\}/\{19.5\ \text{g/dL}\} = 0.043\ \text{L} = 43\ \text{mL}. \quad \textbf{Eq. 93.4}$$

If the volume needed to reach the $Hb_{targeted}$ is greater than the volume of one unit of packed RBCs, blood should be transfused one unit at a time to minimize exposure to multiple donors. Prior to the administration of additional packed RBCs, the Hb concentration should be measured after allowing at least 30 minutes post transfusion for Hb and hematocrit values to equilibrate. The transfusion can be completed with another unit or partial unit if a reasonable Hb level is not attained.

If the volume of packed RBCs required is less than one unit, a partial unit can be given. Whole packed RBC units can be divided in half (standard division) or in small pediatric 75-mL transfer packs (Pedi-Pak). Partial units prepared nonsterilely expire 24 hours after preparation. On the other hand, partial units prepared sterilely can be kept as long as the original unit (up to 42 days for AS–3). A small volume of packed RBC unit placed in a syringe must always be administered within 24 hours.

Length of Storage

Regulatory agencies and scientific societies, such as the Food and Drug Administration and the American Association of Blood Banks, mandate that packed RBC units can be stored up to 42 days based on the premise that at least 75% of transfused RBC will be alive 24 hours post transfusion and that hemolysis will be <1%.[78] However, a *storage lesion* occurs over time, which raises many concerns.[18,79] These storage lesions involve a number of biochemical and biomechanical RBC changes including a depletion of adenosine triphosphate (ATP) and 2,3-DPG, membrane phospholipid vesiculation and loss, protein oxidation, lipid peroxidation of red cell membranes, and loss of RBC deformability.

Prolonged storage changes the supernatant as well as RBC. Studies have noted the generation of cytokines and other bioreactive substances in the storage medium, including histamine, complement, lipids, and cytokines. These bioactive substances may stimulate proinflammatory pathways and perhaps change flow patterns in the microcirculation.[14,16] Other well-documented time-dependent changes to the storage medium are described, including a progressive fall in pH, an increase in plasma potassium, and release of free Hb from hemolyzed RBCs.[17]

It is uncertain that fresher blood products are perfectly safe. The risk of transmission of some infectious diseases, such as malaria, Chagas disease, and intracellular viruses including CMV, herpes type 8, and Epstein-Barr virus, may be greater with fresher blood. Microchimerism is another concern.[80] The risk of contracting a TAGVH is greater with blood stored less than a week.[81,82]

Data from descriptive studies in human beings on the relationship between RBC storage time and outcomes are inconsistent: Some studies suggest that the outcome of transfused critically ill patients is better if transfused with fresher RBC units, whereas other studies do not support this option.[83,84] The Age of Blood Evaluation (ABLE) study, a double-blind randomized controlled trial, enrolled 2510 critically ill adults who were allocated to receive either RBC stored less ≤7 days or standard issue RBCs (the oldest compatible RBC units available in the blood bank were delivered according to a first-in, first-out policy).[85] RBCs in the fresh group were stored 6.1 ± 4.9 days, whereas RBCs in the standard group were stored for 22 ± 8.4 days (p

<0.0001). Mortality at 90 days after randomization was 35.3% in the standard group (430 patients) versus 37% in the fresh group (448 patients) (absolute risk difference: 1.7%; 95% CI: –2.1%, 5.5%). The same trends were observed for all secondary outcomes (major morbidities; length of respiratory, hemodynamic, and renal support; ICU length of stay; and red cell transfusion reactions) or in any subgroups. The trial concluded that fresher RBCs do not decrease adverse outcome in critically ill adults. The RECESS study randomized 1600 participants ≥12 years of age who were undergoing elective complex cardiac surgery and among whom 1098 received RBCs.[86] The shorter-term storage group received RBCs stored ≤10 days, and the longer-term storage group received RBCs stored ≥21 days; the mean durations of RBC storage were 7.8 ± 4.8 days in the shorter-term storage group and 28.3 ± 6.7 in the longer-term storage group. Change in multiple organ dysfunction score was the same in both groups. In addition, 7-day and 28-day mortality and adverse events (except for hyperbilirubinemia, which was more common in the longer-term storage group) did not differ significantly. This large trial also concluded that fresher RBCs were not superior. Three other large randomized controlled trials addressing the same question are ongoing: the Red Cell Storage Duration and Outcomes in Cardiac Surgery (NCT00458783), which will enroll 2600 adults after an elective cardiac surgery; the TRANSFUSE study, which will include 6000 transfused critically ill adults,[87] and the INFORM trial, which will recruit 24,400 hospitalized adults.[88]

Although all of the adult studies may demonstrate that using fresher RBC units does not improve the outcomes of transfused critically ill adults, one can question whether this will hold true in children. Two prospective descriptive studies undertaken in critically ill children suggest that outcome is less favorable with transfusion of packed RBC units stored for more than 2 or 3 weeks.[33,89] A large randomized controlled trial, the Age of Blood in Children in PICU (ABC-PICU) study (NCT01977547) that will enroll 1538 transfused PICU patients should provide definitive evidence. Presently, there is no justification to require fresh RBC units in critically ill children.

Perfusion, Warming, and Filtration

An RBC transfusion must be completed within 4 to 6 hours (4 hours in the United States) after the unit is delivered by the hospital blood bank. A packed RBC unit is usually transfused over 1 to 3 hours, but it can be given more slowly (up to 4 hours) or divided in two transfusions if there is some risk of cardiac overload.[76]

The viscosity of packed RBC units is high, which implies it is preferable to use larger bore needles to administer them. No drugs should be given in the line used for packed RBC unit perfusion. There is in theory a risk of hemolysis if RBCs are given with 0.2% saline or dextrose 10%, but the coinfusion of RBC and hypo- or hypertonic solution seems safe if it is short lasting (a few minutes).[90] It is inappropriate to mix RBC units with Ringer's lactate (risk of coagulation) or calcium.

Packed RBC units must be warmed before administration to diminish the viscosity of the blood product and to avoid hypothermia. Blood viscosity decreases by about 7% for each 1°C increase, thus reducing resistance and making it easier to administer blood products through catheters. RBC units are stored at 1° to 6°C and could cause significant hypothermia if given to a patient without warming. All blood products are warmed to room temperature (about 20°C) before delivery to the bedside.

Warming to body temperature (37°C) may be required for patients weighing less than 10 kg or if large amounts need to be given corresponding to more than 20% to 30% of the circulating blood volume. Standard blood-warming devices must be used to raise the temperature of whole blood or packed RBC units, not microwave ovens that can cause severe hemolysis.

Because all packed RBC units (even prestorage leukocyte-reduced RBC units) contain fibrin, platelets, and WBC aggregates, a filter (with 80-, 179-, or 260-micron pores) must always be used to bind these aggregates before they are administered. Although their cost usefulness has not been determined, filter with 20- to 40-micron micropores are more effective, and some evidence suggests that they can prevent some cases of TRALI. Filters with smaller micropores are not considered standard treatment.

Plasma

Types of Plasma

Plasma is separated from RBCs after collection of whole blood or it is collected using an apheresis machine; it is then frozen for storage to preserve the levels of coagulation factors. The name *fresh frozen plasma* is used if the unit is refrigerated within 8 hours of collection, and the term *frozen plasma* is used if refrigerated within 24 hours of collection. There is a slight reduction in factor VIII levels in frozen plasma, but in clinical practice these two types of plasma are essentially interchangeable.[91] We will use the acronym FP (frozen plasma) in this section to designate both types of plasma units.

FP units are collected from a single donor, whereas units of solvent detergent (SD) plasma (Octaplas, Octapharma) are constituted from a pool of FP collected from approximately 700 donors and processed using the SD process for inactivation of lipid-enveloped viruses. In some countries, only FP may be available, but in many countries fresh FP was still available in the year 2015.

FP units are systematically leukocyte reduced by filtration before storage in many countries, but not in the United States. FP volume is about 200 to 250 mL/unit,[76] whereas the volume of SD plasma is about 200 mL/unit. On average, FP contains one unit/mL of all coagulation factors, but there is significant variability among individual units, which is attributable to biological variation in factor levels among individual donors and differences in processing, storage, and preparation for transfusion.[92] The levels of coagulation factors in SD plasma are more standard with little variation among units, as it is a pooled plasma product. FP is stored at –18°C for up to 1 year after collection. SD plasma can be stored for up to 48 months.

Epidemiologic studies reported that adults transfused with FP are more prone to contract ventilator-associated pneumonia, bloodstream infection, and septic shock (relative risk for all infections: 2.99; 95% CI: 2.28–3.93, $p = 0.02$).[93] A prospective cohort study involving 831 critically ill children reported an increased incidence rate of morbidity and nosocomial infections: The adjusted odds ratio was 3.2 (95% CI: 1.6, 6.6) and 2.3 (95% CI: 1, 5.3), respectively; there was also a significant difference in the adjusted length of PICU stay.[94] FP transfusions are associated with adverse clinical outcomes; this might be attributable to their immunomodulative properties.

Transfusion of Plasma: Indication (When)

Generally, plasma is transfused to correct multiple coagulation factor deficiencies (or single factor deficiencies when no recombinant or plasma-derived coagulation factor concentrates are available) in patients with active bleeding or prior to invasive procedures when no alternative therapies are available or appropriate. Common coagulopathies for which FP may be given include liver disease and symptomatic disseminated intravascular coagulation (DIC). However, the use of plasma to treat DIC is controversial because thrombosis is frequently a component of this disorder.[76] FP can also be given for the emergency reversal of warfarin or vitamin K deficiency when prothrombin complex concentrates are not available.[95] FP is also given to prevent bleeding in patients with abnormal coagulation tests. Guidelines suggest transfusing FP only when the international normalized ratio (INR), the prothrombin time (DIC), or the activated partial thromboplastin time (aPTT) is more than 1.5 × normal, as coagulation factors are generally adequate for hemostasis below this level. However, some data suggest that FP is not effective at normalizing mild abnormalities of coagulation tests, and the potential clinical benefit of FP transfusion seems minimal when the INR is <2.5 or an aPTT is <60.[96]

FP may also be administered during massive transfusion of packed RBC units. Some experts advocate early replacement of FP in a 1 : 1 ratio with RBC units in trauma patients with massive bleeding whereas others suggest that FP transfusions should be guided by the presence of abnormal coagulation test results as previously listed. However, according to a systematic review, application of a thromboelastography (TEG or ROTEM)-guided transfusion strategy did reduce the amount of bleeding in patients with massive transfusion but failed to improve morbidity and mortality.[97] FP or whole blood should be administered in patients who have received more than 150% of their circulating blood volume, even if there is no bleeding, or in patients who have received more than one circulating blood volume and who have clinical evidence of oozing or microvascular bleeding.[95,98]

Plasma exchange is used for thrombotic thrombocytopenic purpura (TTP).[95] There is no evidence that FP should be given in prophylaxis to nonbleeding patients. Plasma should not be used as a volume expander; crystalloids, synthetic colloids, or purified human albumin solutions are preferred.

Transfusion of Plasma: How

One mL of FP contains about one unit of each of the coagulation factors. For most deficiencies, 30% of normal factor activity is enough to ensure hemostasis. Surgical hemostasis may be achieved with factor II levels 5% to 50% of normal, factor V approximately 30% of normal, factor VII 25% of normal, and factor VIII 30% to 60% of normal.[42] It should be appreciated that these data were generated from single factor deficiencies and have never been analyzed in the setting of multiple factor deficiencies that are seen in the vast majority of bleeding patients in the PICU. Practitioners usually administer 10 to 20 mL/kg of plasma initially; this should increase the level of the individual coagulation factors above 30%. As the levels of coagulation factors vary among units, the response to FP is not consistent. Therefore, the effectiveness of FP transfusion should be estimated by clinical judgment of ongoing bleeding and, if necessary, repeat coagulation testing. Additional doses of FP may be required for ongoing bleeding with persistently elevated coagulation

tests. Karam and associates reported that a dose-response relationship was only found in patients with an INR >2.5; patients with lower INR had no significant change in coagulation tests.[96] Normalization of coagulation tests often does not occur and therefore should not be used as the only guide for additional FP transfusions.

FP transfusions should be ABO compatible but are not required to be identical. In contrast to RBC, group AB positive plasma is the universal plasma donor and can be given in emergency situations when a blood group is not available. Cross-matching is not required as FP units are screened for antibodies against non-ABO and Rh antibodies, which may cause hemolytic reactions.

FP must be thawed (20 to 30 minutes) prior to transfusion. Warming FP can be shortened to 7 minutes using microwave ovens specifically constructed for this task (a standard microwave oven can disable coagulation factors). A thawed unit of FP is ideally transfused within 4 hours, but thawed plasma can be relabeled and stored for up to 5 days (American Association of Blood Banks [AABB] Technical Manual). The clinical indications for thawed plasma are similar to FP but there is some decrease in the labile coagulation factors (factor V and VIII). An 80- or 170-micron pore filter must be used.

Platelets

Platelet Transfusion: Why and Why Not

More than 1.5 million platelet products are transfused in the United States each year.[99] Most platelet transfusions are given to increase platelet count. The prevalence of thrombocytopenia, defined by a platelet count <150,000/uL (<150 × 10^9/L), is 17.3% on admission into the PICU; 25.3% of children are thrombocytopenic at some point during their PICU stay.[100] Thrombocytopenia arises from decreased platelet production, increased platelet destruction, and dilutional or distributional causes. In the PICU, most thrombocytopenia is caused by sepsis, disseminated intravascular coagulation, MODS, or hemolytic uremic syndrome. However, heparin-induced thrombocytopenia, massive transfusion, and reactive hemophagocytic syndrome are not so rare. In critically ill children, thrombocytopenia at PICU entry is associated with increased mortality (17.6% versus 2.5%), bleeding complications, thrombosis, and prolonged PICU and hospital length of stay.[100]

Pediatric subjects are at higher risk of bleeding over a wide range of platelet counts, indicating that their excess bleeding risk may be because of factors other than platelet counts.[101] Platelet dysfunction might be the problem, at least in some instances. In PICU patients, it is caused most of the time by specific treatments (cardiopulmonary bypass, hypothermia, pentastarch, and hetastarch) or antiplatelet drugs (low-dose aspirin, nonsteroidal antiinflammatory drugs), but it can also be caused by hereditary disease (eg, Bernard-Soulier disease, etc.). Platelets are important actors in hemostasis. They also have inflammatory functions and can influence both innate and adaptive immune response.[102]

Types of Platelet Products

Standard Platelet Products

Different methods can be used to obtain platelet products: they may be whole

blood–derived platelets—either by the platelet-rich plasma (United States and UK) or the buffy-coat method (Europe and Canada)—or by apheresis (single-donor) platelets (United States, Europe, and Canada). For whole blood–derived platelets, platelet concentrates are often pooled (up to six units) for a single platelet transfusion.

The maximum in vivo platelet life span is 10.5 days.[103] When stored at 20° to 24°C and gently agitated in a continuous manner, stored platelets can be used up to 5 days (up to 7 days in some European countries) after they were collected, but they will become active only 4 hours post transfusion. If they are stored at 4°C, they are active immediately but cannot be stored for more than 48 hours. In practice, most platelets units are stored at 20°C.

Special Platelet Concentrates

Leukocyte-Reduced Platelets

A platelet concentrate must contain $<8.3 \times 10^5$ WBCs to be labeled leukocyte reduced. Prestorage leukocyte reduction is a standard procedure in many countries. A bedside leukocyte reduction filter should not be used when prestorage leukocyte reduction was done because it is useless and can decrease the number of platelets.

Irradiated Platelets

The risk of TAGVH is increased in patients who receive human leukocyte antigen (HLA)–compatible platelets. Therefore, pretransfusion irradiation is mandatory for all HLA-compatible platelet concentrates. Irradiation is also recommended for intrauterine transfusion and infants at risk of TAGVH.[76]

Cytomegalovirus Negative Platelets

Platelet concentrates can transmit CMV. The indications for CMV-negative platelets and RBCs are similar.

Platelets Substitutes

There is no alternative to platelets transfusion. However, cryoprecipitate can be used to treat platelet dysfunction caused by uremia if therapy as dialysis is not successful.[76]

Transfusion of Platelets: Indication (When)

Platelet transfusions are indicated for the prevention or treatment of bleeding in patients with thrombocytopenia or platelet dysfunction. As platelet transfusions will only result in modest elevations for 1 to 3 days in patients with persistent thrombocytopenia, the purpose of platelet therapy is not to eliminate all bleeding but to prevent or stop major hemorrhagic events.

Therapeutic platelet transfusions are given to treat clinically significant bleeding associated with a low platelet count. There is evidence that correction of thrombocytopenia reduces the mortality of critically ill patients,[100,104] but a platelet transfusion should be considered only if the platelet count in an actively bleeding patient is <50,000 to 100,000/uL.

More than 50% of platelet transfusions are given to prevent bleeding, even though the need for prophylactic transfusions has not been conclusively proved. There is insufficient evidence to support a particular threshold for prophylactic platelet transfusion in children. Most recommendations come from guidelines developed for adults, based on expert opinion. For patients with hypoproliferative thrombocytopenia (eg, chemotherapy induced), a platelet transfusion threshold of 10,000/uL is recommended.[76] This is based on two clinical trials in adults: Slichter and colleagues[103] reported no increases in bleeding rates when comparing platelet transfusion thresholds of 10,000 versus 20,000/uL[103]; on the other hand, Stanworth and coworkers[105] reported more bleeding in patients with hematologic cancer and a platelet count <10,000/uL who did not receive prophylactic platelet transfusion versus those who did.

In the ICU, higher platelet transfusion thresholds are usually employed. Intensivists generally prescribe platelets for patients on ECMO if their platelet count is <100,000/uL; the same threshold is frequently used when a central nervous system procedure is undertaken. When the platelet count is <50,000/uL, platelets are usually given just prior to an invasive procedure (surgery, insertion of central venous catheter, etc.); they can also be considered in mechanically ventilated patients because the risk of pulmonary hemorrhage is significant. A threshold of 10,000 or 20,000/uL is recommended for lumbar puncture.

The platelet count must be monitored closely if a large amount—more than one blood volume—of crystalloids or packed RBC units is given because this can significantly dilute the circulating platelet volume.

The platelet count is not the only element to consider when deciding whether to administer platelets: Increasing the threshold that triggers platelet transfusion may be appropriate if a rapid decrease in the platelet count is observed, if the risk of bleeding is high, or if platelets are dysfunctional. Platelets are contraindicated in patients with thrombotic thrombocytopenic purpura and heparin-induced thrombocytopenia because of the increased thrombotic risk.

The capacity of platelets to stop a hemorrhage is related not only to their number but also to their function. Many tests can be used to estimate platelet function like thromboelastography and devices or systems such as the Sonoclot coagulation analyzer, the Plateletworks analyzer, the Hemostatus platelet function test, the Platelet function analyzer, and VerifyNow (Ultegra) System.[42] However, the results of these tests are not available on an emergency basis in most hospitals.[106] Measurement of platelet mass may be a practical alternative. There is evidence that larger platelets exhibit increased hemostatic activity.[107] The results of a randomized controlled trial conducted in a neonatal ICU suggest that using platelet mass (platelet count × mean platelet volume) rather than platelet count to trigger a platelet transfusion may reduce the number of transfusions.[108] Nevertheless, it must be underlined that the clinical usefulness of all these tests remains undetermined in the PICU.

There is a significant diversity in the stated practice pattern with respect to platelet transfusion.[109] Most guidelines are based on experts' opinion, not on hard data.[39,95,110] Additional research must be conducted to better determine when platelets should be given to critically ill children.

Transfusion of Platelets: How

There are about 55×10^9 platelets per unit. A simple rule of thumb suggests giving one or two platelet units per 10 kg but not more than six units per transfusion. For children weighing less than 10 kg, the platelet dose can be 5 to 10 mL/kg of pooled or apheresis platelet unit. Transfusion of one platelet concentrate per m^2 of body surface generally increases the platelet count by 7000 to 11,000/uL. By body weight, the administration of one unit per 10 kg should increase the platelet count by 30,000 to 50,000/uL. However, a clinical trial, where platelet dose was estimated by body surface area, evaluated low- (1.1×10^{12} platelets/m^2), medium- ($2.2 \times 10^{12}/m^2$), and high-dose ($3.3 \times 10^{12}/m^2$) prophylactic platelet transfusions and did not find any differences in bleeding among adult or pediatric patients.[111] Platelets must be used within 4 hours after delivery from the blood bank, but there is some evidence that the platelet count rises more if the unit is given within an hour. A filter with 80- or 170-micron pores must be used to remove aggregates that can form between harvesting and transfusion.

The volume of a platelet-rich unit is about 50 to 70 mL, whereas that of an apheresis platelet unit ranges from 200 to 300 mL; 90% to 95% of this volume is plasma. It is important to note that this plasma is not an adequate source of coagulation factors because their concentration drops rapidly during platelet storage. Platelet units can be volume reduced (removal of plasma) prior to transfusion, but this process can decrease the platelet count by 15% to 20%, shortens the storage time to 4 hours, and delays platelet release from the blood bank by approximately 1 hour. Volume reduction should only be considered if there is a risk of severe cardiac overload, but it is not recommended as a standard procedure because it can activate platelets.[76]

Unlike RBC units, ABO compatibility is not mandatory with platelets. However, it is better to use ABO compatible platelet units in young patients with small blood volume. Moreover it is recommended to deliver ABO compatible platelets when inventory and time permit, unless the plasma component has been substantially reduced. In addition, Rh compatibility is desired because all platelet units contain some RBCs. Transfusion of an Rh-positive unit to an Rh-negative patient can cause Rh alloimmunization; an anti-D immunoglobulin (WinRho) should be administered within 48 hours to prevent this complication when Rh-positive platelets are given to an Rh-negative patient, particularly if female.[99]

The percentage platelet increment (difference between post- and pretransfusion platelet count) should be higher than 20% if the dose is adequate and if a platelet count is performed 10 to 60 minutes post transfusion; it should be higher than 10% if measured 18 to 24 hours post transfusion.[99] Platelet refractoriness can occur due to nonimmune factors such as disseminated intravascular coagulation, in which platelet consumption can be high, acquired hemophagocytic syndrome, with drugs like amphotericin or heparin, or secondary to immune factors involving antiplatelet antibodies.[99] Treatment of the underlying problem is mandatory in such instances (eg, discontinuing all heparin administration in heparin-induced thrombocytopenia). Patients with anti-IgA antibodies should receive washed platelets or platelets collected from IgA-deficient donors.

Cryoprecipitate

Cryoprecipitate is a concentrated source of fibrinogen, factor VIII, factor XIII, and von Willebrand factor. It is stored at a minimum of –18°C for a maximum of 1 year. It is used in patients with congenital or acquired hypofibrinogenemia and patients with coagulopathy and significant bleeding. It can also be used in patients with von Willebrand disease and hemophilia A if specific factor concentrates are not available. The dose is 1 or 2 units/10 kg (maximum: 12 units), which should increase fibrinogen level about 60 to 100 mg/dL.[76] A blood filter (80 or 180 micron) should be used. The recommended rate of delivery is 30 minutes (maximum: 4 hours).

Transfusions Reactions and Complications

Transfusion of labile blood products (RBC, plasma, platelets) can cause immediate or delayed transfusion reactions and various complications. Immediate reactions usually occur during the transfusion or within 6 hours after the end of the transfusion. Delayed reactions can occur after a few days, weeks, or even months or years later.

Transfusion Reactions to Red Blood Cells, Plasma, and Platelets

Immediate Transfusion Reactions

The incidence of typical immediate transfusion reactions after RBC, FP, and platelet transfusion is reported in Table 93.2. The risk of transfusion reactions is higher in children. The SHOT report on transfusion reactions observed in children in the United Kingdom from 1996 to 2005 estimated the incidence of transfusion-related adverse events to be 13 per 100,000 RBC units issued for adults, 18 : 100,000 for children younger than 18 years, and 37 : 100,000 for infants younger than 12 months.[112] Among the 321 adverse reports in children, 82% were instances of incorrect blood component transfusion and 50 cases (14%) were acute transfusion reactions.

TABLE 93.2

Incidence of Transfusion Reactions (Adults and Children)

	RISK PER 1 UNIT OF BLOOD COMPONENT[a]			
	All products	RBC	FP	Platelets[b]
A. Early Transfusion Reactions (Onset Usually <6 Hours Post Transfusion)				
Cardiorespiratory systems:				
—Transfusion-related acute lung injury (TRALI)[a,168]	1 : 31,960	1 : 23,350	1 : 19.783	1 : 15,595
—Transfusion-associated circulatory overload (TACO)[a,168]	1 : 34,091	1 : 32,690	1 : 32,971	–
—Hypotension[a,c,168]	1 : 102,273	1 : 108,968	1 : 98,914	+
—Cardiac arrhythmias[d,169]	+	+	–	–
Hematologic and immunologic systems:				
—Acute hemolytic reactions[a,168]	1 : 26,914	1 : 18,161	–	1 : 31,189
—ABO incompatibility[a,168]	1 : 85,227	1 : 108,968	1 : 98,914	1 : 15,595
—Major allergic reaction (anaphylaxis)[a,168]	1 : 11,117	1 : 23,350	1 : 6182	1 : 3889
—Minor allergic reaction (urticaria)[148]	1 : 100	+	+	+
Other acute transfusion reactions and complications:[e]				
—Febrile nonhemolytic reaction[170,171]	1 : 50 to 1 : 200	1 : 300	–	1 : 10

—Bacterial contamination[a,168]	1 : 51,136	1 : 65,381	1 : 49,457	1 : 31,189
B. Delayed Transfusion Reactions (Onset Usually Days After Transfusion)				
Transfusion-associated graft-versus-host disease[81]	1 : 1 million	+	+	+
Delayed hemolytic transfusion reactions[a,168]	1 : 255,682	1 : 163,452	–	–
Post transfusion purpura[a,168]	1 : 85,227	1 : 108,968	–	1 : 31,189
Transfusion-transmitted nonbacterial infections	See Table 93.4	+	+	+

[a]Reported in 2003.

[b]Risk per pool of five units of platelet.

[c]Hypotension can be caused by allergic or hemolytic reactions, septicemia, citrate toxicity, reaction to leukocyte reduction filters, and bradykinins in the supernatant of blood products.

[d]One retrospective study involving 143 critically ill adults with sepsis or septic shock reported more atrial fibrillation ($p = 0.04$), cardiac arrest ($p = 0.03$), and “all cardiac events” ($p = 0.001$) in recipients of packed RBC units.[169]

[e]Metabolic complications include hypothermia, metabolic alkalosis,[172] hypocalcemia,[173] hypomagnesemia,[172] hyperkalemia,[173] hyponatremia,[17] and hyperglycemia.[174]

FP, frozen plasma; RBC, red blood cell.

Transfusion reactions are probably underdiagnosed in critically ill children. In a study conducted in the PICU of Sainte-Justine Hospital, all transfusions between February 2002 and February 2004 were prospectively monitored.[113] A total of 2509 transfusions were administered to 305 patients; 40 acute transfusion reactions (1.6%) occurred: 24 nonhemolytic febrile reactions, 6 minor and 1 major (anaphylactic shock) allergic reactions, 4 isolated hypotensive reactions, 3 bacterial contaminations, 1 hemolytic reaction, and 1 TRALI.

The most important acute transfusion reactions are described next.

Respiratory System

TRALI (transfusion-related acute lung injury) is one of the most dangerous transfusion reactions. Two pathophysiologic mechanisms are currently proposed.[114,115] (1) According to the antibody hypothesis, TRALI is caused by an antigen-antibody reaction.[116] The antibodies (granulocyte antibodies or HLA class I or II antibodies) are present in the donor plasma and react with the recipient's WBC antigens (or rarely vice versa). The administration of such antibodies can directly injure the lung or can activate neutrophils, monocytes, and complement, creating an inflammatory reaction that may result in pulmonary damage. (2) According to the *two-hit* or *neutrophil priming* hypothesis, recipients must first have a predisposing factor, which *primes* their neutrophils, like a septic state or a MODS; then, the recipient's neutrophils are activated again by donor plasma that contains leukocyte antibody or proinflammatory molecules like cytokines and bioactive lipids.[117]

A panel of experts suggested a consensus definition of TRALI in 2004[118]; the list of diagnostic criteria advocated by these experts is detailed in Table 93.3. The diagnosis of TRALI is made on the basis of clinical signs and symptoms, chest x-ray suggestive of pulmonary edema, and time relationship with transfusion (onset per transfusion or within 6 hours post transfusion). Experts defined TRALI as a new ALI for which no other risk factor than the transfusion can be found. They suggested the term *possible TRALI* if another risk factor can be temporally related to the ALI. TRALI is a clinical syndrome, and no laboratory test is pathognomonic, but the presence of HLA or neutrophil antibodies in the donor plasma is highly suggestive[114]; however, the absence of such antibodies does not exclude a typical case of TRALI. Causes of pulmonary edema other than TRALI should also be excluded, like fluid overload or

cardiac dysfunction.

TABLE 93.3

Diagnostic Criteria of Transfusion-Related Acute Lung Injury (TRALI) and Possible TRALI[175]

Diagnostic Criteria of TRALI (All Four Criteria Must Be Present):
1. Diagnostic criteria of acute lung injury (ALI): —Acute onset —Hypoxemia: $PaO_2/FiO_2 \leq 300$ or $SpO_2 < 90\%$ on room air —Bilateral infiltrates on frontal chest radiograph —No evidence of left atrial hypertension (ie, no circulatory overload) 2. No preexisting ALI before transfusion 3. Onset during or within 6 hours post transfusion 4. No temporal relationship to an alternative risk factor of ALI (see list of factors[a])
Diagnostic Criteria of Possible TRALI:
Acute lung injury (ALI)
No preexisting ALI before transfusion
Onset during or within 6 hours posttransfusion
A clear temporal relationship to an alternative risk factor for ALI

[a]Risk factors of direct lung injury: aspiration, pneumonia, toxic inhalation, lung contusion, near drowning. Risk factors of indirect lung injury: severe sepsis, shock, multiple trauma, burn injury, acute pancreatitis, cardiopulmonary bypass, drug overdose.

The incidence rate of TRALI in the PICU is unknown, but there is evidence that it is underreported.[119,120] Over a 3-year period, Gauvin and colleagues[113] observed one case of TRALI among 305 transfused PICU patients.

All blood products that contain plasma, even in minute quantities, can cause a TRALI. When such a reaction occurs, the transfusion must be stopped immediately and supportive therapy administered. Associated hypotension may be unresponsive to fluid administration and may require the use of inotropes/vasopressors. Diuretics are not useful and are contraindicated in hypotensive patients. All suspected TRALI reactions must be reported to the blood bank, because the donor's other blood products have to be withdrawn.

The prognosis of cases of TRALI is usually good if the patient survives, but a mortality rate of 6% has been reported. In survivors, resolution is usually rapid (within 96 hours) and there are no long-term sequelae.[121]

The diagnostic criteria advocated by the panel of experts in 2004 exclude the possibility that a TRALI appears more than 6 hours post transfusion or in patients who already present an ALI or ARDS, a frequent occurrence in the PICU. Marik and coworkers[122] suggested expanding the definition of TRALI in ICU to ALI/ARDS observed within 72 hours after the transfusion of a blood product: They reported that such “delayed TRALI syndrome” occurred in up to 25% of transfused critically ill adults. Church and associates[123] also reported an association between the transfusion of plasma or packed RBC units and ALI/ARDS. There is also some evidence that TRALI should also be considered in some patients with ALI/ARDS before a transfusion if their respiratory dysfunction deteriorates significantly during or after a transfusion.[124] The bioactive substances contained in packed RBC and plasma units can cause or add to the severity of cases of ALI/ARDS.[123,125] Actually, there is a synergistic effect of anemia and RBC transfusion on inflammation and lung injury.[126] Further investigation is required to better characterize the epidemiology, the mechanisms, and the clinical impact of transfusion-related ALI/ARDS in the PICU.

Respiratory Dysfunction Associated With Transfusion.

Respiratory complications associated with RBC transfusions may be underestimated in the PICU because current definitions exclude patients with preexisting respiratory dysfunction (RD). Emeriaud and colleagues[124] undertook a prospective cohort study to determine the epidemiology of new or progressive RD observed after RBC transfusion in critically ill children. A respiratory dysfunction associated with transfusion (RDAT) was considered new if it appeared after the first RBC transfusion in the PICU. A progressive RDAT was diagnosed if an RD was present before the transfusion and the PaO_2/FiO_2 or SpO_2/FiO_2 ratio dropped by at least 20% thereafter. Among 136 transfused patients, 58 cases of RDAT (43% of transfused patients) were detected, including 9 (7%) new RDAT and 49 (36%) progressive RDAT. Higher severity of illness, MODS prior to transfusion, and volume (mL/kg) of RBC transfusion were independently associated with RDAT. A dose-response relationship was observed between transfusion volume (mL/kg) and the incidence of RDAT. Patients with RDAT developed more MODS, had a longer duration of intubation and PICU length of stay, and had higher mortality. The conclusion was that RDAT is frequent in the PICU and occurs mainly in patients with prior RD, who would not be identified using current definitions for transfusion-associated respiratory complications. RDAT is not recognized as a transfusion reaction by the hemovigilance system, but it seems to be a clinically significant transfusion complication. RDAT should be further studied, given the high incidence and the serious adverse outcomes associated with it.

Cardiovascular System

Transfusion-Associated Circulatory Overload.

Transfusion-associated circulatory overload (TACO) is presently the leading cause of transfusion-related morbidity and mortality in North America.[127] From 2000 to 2009, 730 cases of TACO were reported to the Quebec Hemovigilance System.[128] In 2013, 96 cases of TACO were collected by the British Haemovigilance Scheme; none were reported in children.[127]

TACO in critically ill adults is underreported to hemovigilance systems.[125,129-133] There are almost no data on TACO in the PICU.[89,94,113,119,120,134-137] The risk of contracting a TACO is likely higher in children in the PICU because cardiac dysfunction, a well-recognized risk factor for TACO, is common in PICU patients.[127,138] Indeed, it may be that TACO is not reported to the hemovigilance system in critically ill children probably because the diagnostic criteria of TACO are not well suited to children.

Two sets of diagnostic criteria of TACO are presently used:

1. TACO definition, according to the US Biovigilance Network (www.aabb.org/programs/biovigilance/Documents/diagnose_full.html)—New onset or exacerbation of three or more of the following within 6 hours of cessation of transfusion: (1) acute respiratory distress (dyspnea, orthopnea, cough), (2) evidence of positive fluid balance, (3) elevated brain natriuretic peptide (BNP), (4) radiographic evidence of pulmonary edema, (5) evidence of left heart failure, (6) elevated central venous pressure.

2. TACO definition, according to the British Haemovigilance Scheme (Serious Hazards of Transfusion [SHOT]) and the International Society of Blood Transfusion (ISBT)[139]—TACO is present if at least four or the five following criteria are met within 6 hours of transfusion: (1) acute respiratory distress, (2) tachycardia, (3) increased blood pressure, (4) acute or worsening pulmonary edema, (5) evidence of positive fluid balance.

In 2009, no TACO was reported in a prospective cohort study of 136 consecutive PICU patients transfused with RBC.[140] A subsequent chart review was undertaken to ascertain whether TACO cases had been missed. Attempts to use the criteria advocated by the British Haemovigilance Scheme[119] were problematic because terms such as *tachycardia* and *increased blood pressure* were vaguely defined and did not provide age-adjusted reference ranges. When using diagnostic criteria that compared heart rate or blood pressure with normal pediatric values or that assessed change between pre- and posttransfusion value, it was noted that the incidence rate of TACO could have ranged from 1.5% to 46% depending on the set of diagnostic criteria used. TACO is probably frequent in the PICU. Its epidemiology can differ significantly if appropriate diagnostic criteria are not used; this implies that better diagnostic criteria must be developed.

TACO is most commonly associated with a rapid or massive transfusion that causes pulmonary edema secondary to heart failure.[141] Reduced cardiac reserve, chronic and severe anemia (Hb <5 g/dL), and age (infants and elderly patients) are risk factors. The main symptoms are respiratory distress, hypoxemia, tachycardia, and hypertension. When TACO is suspected, transfusion must be stopped and supportive treatment provided. Slow transfusion (≤1 mL/kg/h) for at-risk patients can prevent TACO.

Hypotensive reactions are increasingly recognized,[142] but their etiology remains uncertain. They are probably attributable to bradykinin generation, which can happen when a blood product is exposed to negatively charged surfaces (eg, filters). The risk of hypotensive reaction is increased in patients receiving angiotensin conversion enzyme inhibitors (ACEI) or with diminished bradykinin metabolism. Hypotensive reactions are more frequently associated with platelets than with RBC and plasma. However, the authors observed only five platelet-related hypotensive episodes among 3672 consecutive PICU admissions.[143] Transfusion-related hypotension may happen alone or with some flushing; it occurs rapidly after the transfusion begins. The treatment is straightforward: The transfusion must be stopped and supportive treatment (ie, fluid bolus) should be undertaken.

Other Acute Transfusion Reactions.

Nonhemolytic febrile reaction is the most frequent and benign acute transfusion reaction (1 in 300 RBC and 1 in 20 platelet transfusions).[144] In addition to fever, it can be accompanied by chills, discomfort, headache, nausea, or vomiting. The symptoms usually occur toward the end or soon after a transfusion. These reactions are mediated by pyrogenic substances that accumulate during storage or by the recipient's antibodies that bind with leukocytes from the donated blood, which allow activation of the complement system and production of cytokines. Acetaminophen can be used to minimize fever, but premedication with acetaminophen, diphenhydramine, or steroids is not useful. A decrease in the incidence of these

reactions is reported with prestorage leukocyte reduction.[145,146]

Acute hemolytic reactions may be much more serious. They are caused by lysis or accelerated destruction of RBCs due to immunologic incompatibility between donor and recipient blood. The mortality rate associated with transfusion errors is <10%.[147] ABO mismatch is the most frequent and most severe of the blood group incompatibilities, with hemolysis and death as the results. In most instances, mistransfusion is the cause—that is, the patient receives a packed RBC unit that was prepared for another patient. The risk that such errors happen is obviously higher in the context of emergency transfusion; its prevention warrants careful verification by medical staff of all blood products administered. The reaction is characterized by fever, chills, discomfort, diffuse pain, and hemoglobinuria; hypotension, shock, renal failure, and disseminated intravascular coagulation are also observed in some cases. When such a reaction is suspected, the transfusion must be stopped immediately and supportive treatment administered. To avoid these hemolytic reactions, donor and recipient compatibility must be thoroughly checked (ABO and Rh types, unit identification number) and the recipient must be properly identified (name and medical record number) when the sample is taken for pretransfusion analyses as well as before the transfusion begins. Several centers have instituted double verification by two different individuals for every assessment made.

Nonimmune hemolysis can be caused by mechanical trauma to RBCs, rapid administration through a small catheter, excessive warming or freezing, or contact with hypotonic solution.

Allergic transfusion reactions result from the interaction between donor allergens and recipient antibodies (IgE) that provokes a type I hypersensitivity reaction.[148] Other possible mechanisms include preexisting class-specific anti-IgA in patients with IgA deficiency, preexisting antibodies to polymorphic forms of other serum proteins (IgG, albumin, haptoglobin, etc.) that the patient is lacking, transfusion of allergens to which a patient is presensitized (drugs, chemicals, etc.), and passive transfer of IgE antibodies to transfused patients.[148] The reaction can be minor (eg, isolated urticaria) or major (eg, hypotension, anaphylactic shock, respiratory distress, digestive disorders). A severe reaction usually occurs quickly, whereas a benign reaction may occur up to 4 hours after the transfusion has been completed. When an allergic reaction is suspected, the transfusion must be stopped and supportive treatment undertaken with antihistamines, corticosteroids, and epinephrine if required. Prevention must be considered. Premedication of patients with antihistamines is suggested if they have already presented two minor episodes. In patients with major reactions, premedication can be used with corticosteroids and antihistamines. Washed RBC and platelets units can also be used. Patients with anti-IgA antibodies must receive blood products from donors with IgA deficiency or products that have been washed several times. Leukocyte reduction does not offer any benefit.

Bacterial contamination is more frequent with platelets than with RBC units or plasma because platelet concentrates are stored at 20° to 24°C. Contamination may be due to unsuspected bacteremia in the donor, skin flora contamination when taking a blood sample from the donor, or issues related to product handling. The most common microorganisms identified are gram-negative bacteria such as *Klebsiella pneumoniae*, *Serratia marcescens,* and *Pseudomonas species,* and gram-positive bacteria such as *Staphylococcus aureus, Staphylococcus epidermidis*, and *Bacillus cereus*.

The reaction is characterized by fever and chills and may lead to septic shock. Symptoms usually appear during or within 4 hours after transfusion. When bacterial contamination is suspected, transfusion must be stopped immediately, wide-spectrum antibiotics must be given (third-generation cephalosporin or beta-lactam in combination with aminoglycoside), and supportive treatment administered. The blood bank must be informed immediately, as other blood products from the same donor may need to be withdrawn.

Many descriptive studies have reported an association between RBC transfusion and necrotizing enterocolitis (NEC) in very low-birth-weight neonates.[149,150] The relevance of *transfusion-related acute gut injury (TRAGI)* in PICU patients is undetermined.

Delayed Transfusion Reactions.

Among the 321 adverse events reported in children by SHOT in UK from 1996 to 2005,[112] there were five cases of severe delayed transfusion reactions, including two cases of TAGVH disease. *TAGVH* is rare but very serious.[81,82] It may occur when viable lymphocytes from a donor are infused to a recipient who is unable to reject them because of immune suppression or partial HLA matching (closed-donor genetic profile). Donor leukocytes can then persist in the recipient, because these lymphocytes recognize the recipient's HLA antigens as foreign and an immune reaction is triggered. Signs and symptoms (generalized skin rash, diarrhea, abnormal liver function, or fever) appear 8 to 10 days after transfusion.[151] Associated complications are aplastic anemia with pancytopenia, which may lead to hemorrhage and severe infections. The mortality rate is 90%. The risk of TAGVH is higher in premature babies and if a patient with a congenital or acquired immunodeficiency receives a nonirradiated RBC unit or if the blood was a directed donation collected from a relative. Neoplasia (eg, leukemia, solid tumors), chemotherapy and transplantation (stem cell, bone marrow, solid organ),[144] intrauterine transfusions, and exchange transfusions are other risk factors. No effective treatment is recognized. Prevention can be accomplished by irradiating blood products.

Delayed (extravascular) hemolytic reactions result from the interaction between recipient irregular alloantibodies and donor RBCs. They involve either antibodies that were present prior to transfusion, but were missed because they were undetectable by cross-matching, or antibodies that appear after the transfusion. Involved antibodies are usually E, Jk^a, c, Fy^a, or K.[144] These reactions occur 3 days to 2 weeks after the transfusion. Symptoms include anemia and jaundice. The outcome is usually good except in some patients with sickle cell anemia. There is no specific treatment.

Posttransfusion purpura is characterized by dramatic, sudden, and self-limiting thrombocytopenia. The pathogenesis is unclear but is presumably related to the development of platelet-specific antibody following transfusion. The platelet count drops below <10,000/uL 5 to 10 days after transfusion was given in a patient with a history of sensitization by pregnancy or prior transfusion.[152] Purpura and diffuse hemorrhages (mucosal, gastrointestinal, urinary, cerebral) may be observed. The thrombocytopenia is refractory to platelet transfusion. The mortality rate is 8%. Treatment includes corticosteroids, plasmapheresis, and immunoglobulins.

Complications Related to Massive Transfusion

Massive transfusion is defined as the administration of more than one circulating volume of blood products within 24 hours, or more than 50% of the circulating blood volume in 3 hours or less, or 10 RBC units in adults.[153] A number of complications may occur: (1) coagulopathy and dilutional thrombocytopenia, which may trigger bleeding; (2) hypothermia due to a rapid infusion of cold blood products, which can lead to arrhythmias, platelet dysfunction, and cardiac dysfunction; (3) citrate toxicity that may trigger hypocalcemia, hypomagnesemia, and metabolic alkalosis; and (4) hyperkalemia.[144] These complications can be avoided by various measures including the use of a blood warmer if the transfusion rate exceeds 50 mL/kg/h, close monitoring of the coagulation profile, platelet transfusion to maintain a count >50,000/uL, plasma administration to attain an INR <1.5 to 2, cryoprecipitate administration to attain a fibrinogen level over 0.1 g/dL, monitoring of hypocalcemia, and calcium supplementation, as required.

Transfusion-Transmitted Infections

In the United States, blood donation is tested at least for the following infectious agents: hepatitis A, B, and C; human immunodeficiency virus (HIV); human T-cell lymphotropic virus (HTLV); West Nile virus (seasonal); and syphilis.[76] These tests and better donor selection have resulted in a significant decrease in the risk of transfusion-transmitted infectious diseases. However, there will always be some residual risk, attributable to the *window period* (the time from the beginning of an infection to the time when tests can detect the infection) and to false-negative results. Emerging pathogens can also be a problem.[154] Table 93.4 lists the risks of contracting specific infections with transfusion.

TABLE 93.4

Transfusion-Transmitted Infectious Diseases in Canada

Infection	Risk per Units Component[a]
Human immunodeficiency virus (HIV)[176]	1 in 8 to 12 million
Hepatitis B[176]	1 in 1.1 to 1.7 million
Hepatitis C[176]	1 in 5 to 7 million
Parvovirus B19[176]	1 : 5000 to 1 : 20,000
Cytomegalovirus[176]	Rare
Syphilis[176]	<1 in 100 million
Other infections[b]	Low

[a]Most transfusion-transmitted infections are attributable to red blood cell units. However, there is historical evidence that the following infectious agents can be transmitted by plasma-derived products: HIV, hepatitis B and C, and parvovirus B19 but not cytomegalovirus or parasites.[168]

[b]Many other agents can be transmitted by a transfusion, like West Nile virus, insect-borne zoonoses (for example, malaria,[177] babesiosis,[178] Bartonella quintana[179]), and variant Creutzfeldt-Jakob disease[180]).

Transfusion-Related Immunomodulation

There is strong evidence that transfusions might generate or enhance both anti- and proinflammatory reactions. Clinically important immune suppression is described in recipients of RBC units. This immune suppression might explain the increased rates of nosocomial infections reported in transfused critically ill patients.[93,155-157]

On the other hand, many proinflammatory molecules are found in plasma-rich

blood products, which may initiate, maintain, or enhance an inflammatory process. The WBC and these substances may trigger or maintain a systemic inflammatory response syndrome (SIRS) in the transfusion recipients. Administering a transfusion to a critically ill patient with SIRS may stimulate the patient's inflammatory syndrome and constitute a *second hit,* which can cause additional organ dysfunction, contribute to MODS,[158] and perhaps ultimately result in higher mortality rates.[53,83,159-161] Some clinical data suggest that these risks decrease significantly if the blood product is leukocyte reduced prior to storage.[162] However, in vitro data suggest that some inflammatory mediators are active even in leukocyte-reduced packed RBC units.[163] One pediatric prospective study indicated that the immune response to RBC transfusion was altered according to the storage age of the cells transfused, although in this small study there were no differences in clinical outcomes.[163a] The clinical impact of transfusion on the immunologic responses of critically ill children remains to be determined.

Complications Specific to Plasma Transfusion

Overall the noninfectious and infectious complications associated with FP are similar to those of RBC transfusions, excluding hemolysis. The most notable risks associated with FP transfusion are TRALI. There are antibodies and other biologically active substances in plasma, but hemovigilance data suggest that SD plasma and a male-predominant plasma transfusion strategy are associated with a reduced incidence of TRALI.[164] FP is known to have immunomodulatory properties,[165] which may explain why plasma is associated with an increased risk of complications associated with transfusion-related immunomodulation. Epidemiologic studies have shown that adults and children transfused with plasma are more prone to contract nosocomial infections.[94] Additionally, large volumes of FP transfused can result in TACO. Allergic reactions are also relatively common with FP transfusions (1%–3%).

The risk of transfusion-transmitted viral infections is the same for FP and RBC units. SD plasma has a reduced risk of infection related to enveloped viral pathogens, and SD donors are tested for nonenveloped viruses, but the risk could be higher with regard to emerging nonenveloped viruses.

Complications Specific to Platelet Transfusion

Major allergic reactions and bacterial contamination are the most frequent severe complications associated with platelet transfusion.[166] Serious noninfectious complications of platelet transfusion are similar to those reported with plasma and RBC with the exception of hemolytic transfusion reactions. Rarely, hemolytic transfusion reactions can be seen after the transfusion of non-ABO identical platelets, which contain anti-A or anti-B antibodies. Platelet transfusion may also be associated with specific adverse effects including platelet refractoriness due to HLA alloimmunization. Prestorage leukocyte-reduced platelet products are available in most North American blood banks, which significantly decreases the risk of HLA alloimmunization and platelet refractoriness, nonhemolytic febrile reactions, and CMV transmission.

The most important infectious complication associated with platelet transfusion is bacterial infection. As platelet concentrates are stored at room temperature, the

incidence of bacterially contaminated platelet products is higher than with RBCs. The risk of bacterial infection can be significantly reduced, but not eliminated, by bacterial testing (eg, routine culture). Pathogens can also be inactivated by different methods using ultraviolet light.[167] The risk of other transfusion-transmitted infections is similar for platelets and other blood components.

Treatment of Transfusion Reactions

Patients should be monitored closely while receiving a transfusion. Vital signs should be taken before transfusion as well as within the first 15 minutes and every hour up to 4 hours after transfusion. The following symptoms and signs suggest that an acute blood reaction has occurred: fever, shivering (rigors), pain, anxiety, agitation, dyspnea, hypotension, hypertension, hemorrhage, shock, and hemoglobinuria (pink or red urine).

If a transfusion reaction is suspected, the transfusion must be stopped immediately, an intravenous access with NaCl 0.9% must be maintained, all measures to ensure patient stability must be undertaken, verification that the patient received the correct unit must be ascertained, a visual inspection of the unit must be conducted and described in the patient hospital chart, clinical data on the event must be detailed in the hospital chart, and the patient should be monitored for at least a few hours. In many centers, the unit that was being transfused, the filter and the tubing being used, and the remaining blood product are returned to the blood bank. A workup must be done to assess for infection as well as to measure antibodies, antigens, free Hb, and sometimes other markers of metabolic disturbance (acidosis, hyperkalemia, hypocalcemia, etc.). All possible transfusion reactions must be reported to the appropriate blood agency or hemovigilance system, which is the blood blank in many hospitals.

Conclusion

A transfusion can save a life but can also cause significant problems. The risk of death attributable to transfusion of a labile blood product is low: Only 1 death over 2,845,459 blood component units was reported in the United Kingdom in 2008.[4] However, serious reactions and severe complications can happen. A transfusion is a serious matter: It should be prescribed only if deemed necessary. Closed monitoring of the recipient is mandatory while a transfusion is given.

CHAPTER 94

Hematology and Oncology Problems in the Intensive Care Unit

Jesse Wenger, Rebecca Gardner, Joan S. Roberts

PEARLS

- Proactive treatment measures for tumor lysis syndrome include hydration with hypotonic or isotonic saline solution, alkalinization, use of allopurinol or urate oxidase, avoidance of exogenous potassium, close monitoring of fluid status, and frequent monitoring of serum potassium, sodium, chloride, bicarbonate, calcium, phosphorus, uric acid, blood urea nitrogen, and creatinine concentrations.
- Clinically significant hyperleukocytosis occurs with a white blood cell count greater than 200,000/μL in acute myeloid leukemia and greater than 300,000/μL in acute lymphocytic leukemia.
- Concurrent thrombocytopenia and hyperleukocytosis increase risk of adverse outcomes including intracranial hemorrhage and death. Aggressive therapy to correct coagulopathy with fresh-frozen plasma and vitamin K and to maintain platelet count greater than 20,000/μL is critical.
- Oxygen consumption may become delivery dependent when the hemoglobin concentration falls below 5 g/dL.
- Signs of significant cardiovascular compromise may not become evident until the child has acutely lost at least 25% of total blood volume.
- In the absence of other hemorrhagic risks, platelet counts 10,000/μL and greater are associated with little risk of serious bleeding.
- Gastrointestinal bleeding is an important cause of morbidity and mortality in patients with end-stage renal disease.
- Intravenous administration of desmopressin acetate at a dosage of 0.3 μg/kg over 30 minutes improves platelet dysfunction caused by uremia within 1 hour, and the effect is maintained for 4 to 8 hours.
- Childhood mediastinal masses produce few symptoms until they have occluded a substantial portion of the cross-sectional area of the trachea or main stem

bronchi or the superior vena cava. Diagnosis should be established with the least invasive means available, because these patients are at significant risk for anesthetic complications.

- Spinal cord compression most frequently occurs as metastatic disease and requires emergent treatment with 1 mg/kg of dexamethasone over 30 minutes.
- Hemophagocytic lymphohistiocytosis (HLH) produces severe illnesses that may be confused with other forms of systemic inflammatory response syndrome, such as sepsis. Appropriate diagnosis is tantamount as untreated HLH is almost always fatal.

Hematologic Emergencies

Anemia

Anemia results from a deficiency in the oxygen-carrying capacity of the blood. The deficit may be in the number of red blood cells (RBCs), the RBC hemoglobin concentration, or both. Because hemoglobin serves as the primary transport molecule for oxygen, anemia may affect the delivery of oxygen (O_2) to the tissues with wide-ranging potential complications (see also Chapters 89 and 93).

Under steady-state conditions, oxygen consumption remains constant and is independent of oxygen delivery until it falls below a critical level, which varies for each organ system. When the hemoglobin concentration decreases to approximately 5 g/dL or less, oxygen delivery and consumption may be altered. Below this level, O_2 consumption becomes delivery dependent.

The body responds to acute, normovolemic anemia by increasing cardiac output, through increases in stroke volume, heart rate, or both. As the hematocrit falls, blood viscosity diminishes, thus increasing venous return and augmenting preload. In the patient with chronic anemia, increases in cardiac output are supplemented by increased levels of 2,3-diphosphoglycerate shifting the oxyhemoglobin curve to the right and augmenting O_2 delivery at the tissue level.

Anemias generally are classified either by the mechanism resulting in the hemoglobin deficit—decreased production, accelerated destruction, or loss of erythrocytes—or by the morphologic appearance of the erythrocyte (Box 94.1).[1]

Box 94.1

Physiologic Classification of Anemia

A Disorders of Red Cell Production in Which the Rate of Red Cell Production Is Less Than Expected for the Degree of Anemia

1. Marrow failure

a. Aplastic anemia

(i) Congenital

(ii) Acquired

b. Pure red cell aplasia

(i) Congenital

(ii) Diamond-Blackfan syndrome

(iii) Aase syndrome

(iv) Acquired

(v) Transient erythroblastopenia of childhood

(vi) Other

c. Marrow replacement

(i) Malignancies

(ii) Osteopetrosis

(iii) Myelofibrosis

(iv) Chronic renal disease

(v) Vitamin D deficiency

d. Pancreatic insufficiency–marrow hypoplasia syndrome

2. Impaired erythropoietin production

a. Chronic renal disease

b. Hypothyroidism, hypopituitarism

c. Chronic inflammation

d. Protein malnutrition

e. Hemoglobin mutants with decreased affinity for oxygen

B Disorders of Erythroid Maturation and Ineffective Erythropoiesis

1. Abnormalities of cytoplasmic maturation

a. Iron deficiency

b. Thalassemia syndromes

c. Sideroblastic anemias

d. Lead poisoning

2. Abnormalities of nuclear maturation

a. Vitamin B_{12}; deficiency

b. Folic acid deficiency

c. Thiamine-responsive megaloblastic anemia

d. Hereditary abnormalities in folate metabolism

e. Orotic aciduria

3. Primary dyserythropoietic anemias (types I, II, II, IV)

4. Erythropoietic protoporphyria

5. Refractory sideroblastic anemia with vacuolization of marrow precursors and pancreatic dysfunction deficiency

C Hemolytic Anemias

1. Defects of hemoglobin

a. Structured mutants

b. Synthetic mutants (thalassemia syndromes)

2. Defects of the red cell membrane

3. Defects of red cell metabolism

4. Antibody mediated

5. Mechanical injury to the erythrocyte

6. Thermal injury to the erythrocyte

7. Oxidant-induced red cell injury

8. Infectious agent-induced red cell injury

9. Paroxysmal nocturnal hemoglobinuria

. Plasma lipid-induced abnormalities of the red cell membrane

Morphologic classifications of anemia are based on either erythrocyte size, as defined by mean corpuscular volume and mean corpuscular hemoglobin concentration, or abnormalities in the erythrocyte shape (Box 94.2).[1] The normal values for mean corpuscular volume and mean corpuscular hemoglobin concentration vary with the child's age. A wide variety of conditions, some intrinsic to the erythrocyte and others related to extrinsic factors, may result in abnormal RBC morphology. The more common causes of profound anemia encountered in the pediatric intensive care setting are reviewed here.

Box 94.2

Classification of Anemias Based on Red Cell Size

A Microcytic Anemias

1. Iron deficiency (nutritional, chronic blood loss)

2. Chronic lead poisoning

3. Thalassemia syndromes

4. Sideroblastic anemias

5. Chronic inflammation

6. Some congenital hemolytic anemias with unstable hemoglobin

B Macrocytic Anemias

1. With megaloblastic bone marrow

a. Vitamin B_{12} deficiency

b. Folic acid deficiency

c. Hereditary orotic aciduria

d. Thiamine-responsive anemia

2. Without megaloblastic bone marrow

a. Aplastic anemia

b. Diamond-Blackfan syndrome

c. Hypothyroidism

d. Liver disease

e. Bone marrow infiltration

f. Dyserythropoietic anemias

C Normocytic Anemias

1. Congenital hemolytic anemias

a. Hemoglobin mutants

b. Red cell enzyme defects

c. Disorders of the red cell membrane

2. Acquired hemolytic anemias

a. Antibody mediated

b. Microangiopathic hemolytic anemias

c. Secondary to acute infections

3. Acute blood loss

4. Splenic pooling

5. Chronic renal disease (usually)

Hemorrhagic Anemia

Bleeding may be either acute or chronic. Chronic bleeding generally causes anemia through depletion of iron stores. In response, patients adopt mechanisms to increase O_2 delivery and to avoid hypovolemia, permitting them to tolerate hemoglobin levels well below the normal range, with mild clinical findings. Signs and symptoms of acute hemorrhage result from poor end-organ perfusion, with consequent

diminished O_2 delivery. Diagnosis of the presence and degree of blood loss may be difficult in an otherwise healthy child. Signs of impending shock, such as pallor, anxiety, and tachypnea, may be subtle. Signs of significant cardiovascular compromise may not become evident until the child has lost at least 25% of total blood volume when patients usually manifest age-related systolic hypotension.[2] Initial management should include achieving hemostasis, establishing a secure airway, maintaining ventilation, and initiating volume replacement via an adequate intravenous catheter.

RBC transfusion should be given if O_2 delivery to the end organ is impaired. Either whole blood or packed RBCs can be used, but the former has many difficulties related to storage and transport (see also Chapter 93). If packed RBCs or plasma-poor red cells are used to correct O_2-carrying capacity during massive blood loss, deficits of coagulation factors develop earlier than during transfusion of whole blood. Hypofibrinogenemia generally develops first, followed by deficits in other clotting factors and later by thrombocytopenia. Fresh-frozen plasma should be used to treat coagulopathy that develops during replacement of massive blood loss with packed RBCs. Other clinical abnormalities associated with replacement of large volumes of RBCs include hyperkalemia, hypocalcemia, and transfusion reactions. Transfusion of platelets should be guided by serial platelet counts. Central venous pressure should be monitored to allow for rapid administration of RBCs and volume replacement while decreasing the risks of hypervolemia. Blood and other fluids may be administered rapidly until central venous pressure rises to 6 to 7 mm Hg.

Anemia Secondary to Bone Marrow Failure

Several hematologic diseases are associated with diminished blood cell production. Acquired aplastic anemia, characterized by pancytopenia and hypocellular or acellular bone marrow, is defined by at least two of the three following: granulocytes less than 500/μL, platelets less than 20,000/μL, and anemia with a corrected reticulocyte count less than 1%, in conjunction with markedly hypocellular bone marrow.[3] The majority of cases have no definable cause but the pathophysiology appears immune mediated with destruction of blood-forming cells by lymphocytes. Excessive production of interferon-γ, tumor necrosis factor, and interleukin-2 has been noted. Altered immunity results in CD34 cell death and in intracellular pathways leading to cell cycle arrest.[4] Cases may follow chemical or drug exposure, as well as a posthepatitis aplastic anemia typically seen in young males, with pancytopenia presenting several weeks after severe liver inflammation. Acquired aplastic anemia can be distinguished from bone marrow failure resulting from Fanconi anemia by specific assays, called *chromosomal breakage studies,* that quantify chromosomal susceptibility to chemical cross-linking agents that characterize Fanconi anemia.[5] Cytogenetic studies usually are normal in aplastic anemia, whereas aneuploidy or structural abnormalities are relatively common in myelodysplasia. Myelodysplasia may evolve in patients treated for aplastic anemia. Some patients with paroxysmal nocturnal hemoglobinuria develop bone marrow failure; conversely, paroxysmal nocturnal hemoglobinuria may evolve years after aplastic anemia is diagnosed.

Irrespective of the etiology of bone marrow failure, life-threatening complications may arise from blood cytopenias. The most common causes of death are bacterial

sepsis and fungal infection secondary to refractory granulocytopenia. Broad-spectrum antibiotics should be used to treat suspected infection in the granulocytopenic patient. Historically, gram-negative organisms were the most frequent cause of fulminant infection in this patient population. With the increased use of central venous catheters, gram-positive organisms now predominate.[6] Antifungal therapy should be instituted in patients who fail to defervesce within 3 to 5 days of treatment with antibiotics. Persistent, unexplained fever requires thorough evaluation to look for evidence of invasive fungal infection.

Platelet transfusions should be used judiciously in an effort to avoid alloimmunization to platelet antigens and are generally reserved for episodes of active bleeding. Similarly, RBC transfusions should be reserved for patients whose oxygen delivery may be compromised as a result of profound anemia. The patient should not receive blood products donated by family members to avoid sensitization to leukocyte and platelet antigens of potential bone marrow donors. All blood products should be irradiated and leukodepleted to decrease the risk of graft-versus-host disease, with preference given to single-donor apheresis units. Treatment of severe acquired aplastic anemia involves either the use of immunosuppressive therapy or replacement of bone marrow through stem cell transplantation. The treatment of choice, bone marrow or peripheral blood stem cell transplantation from a histocompatible sibling, produces long-term survival rates of 75% to 80%.[7] Unfortunately, up to 70% of patients may lack a suitably matched sibling donor. Stem cells harvested from a matched unrelated donor, or umbilical cord blood, produce poorer outcomes because of the higher rate of graft-versus-host disease. For these patients, immunomodulation, which usually includes a combination of antithymocyte globulin and cyclosporin, often with use of hematopoietic growth factors, has resulted in response rates of 70% to 80%.[8] Not all responders achieve a complete remission. Late relapses, as well as evolution to myelodysplasia and leukemia, are reported.

Hemolytic Anemia

Hemolysis, the destruction of RBCs with liberation of hemoglobin, may occur within either the blood vessels (intravascular hemolysis) or the reticuloendothelial system (extravascular hemolysis). Anemia results when the rate of RBC destruction exceeds new RBC production in the bone marrow. Laboratory findings in patients with hemolytic anemia usually include increased reticulocyte count and elevated serum concentrations of unconjugated bilirubin and lactate dehydrogenase. Intravascular hemolysis usually results in decreased serum haptoglobin concentrations.

Premature destruction of RBCs may result from intrinsic RBC abnormalities, such as hemoglobinopathies, from red cell membrane defects, or from a variety of extrinsic factors (Fig. 94.1).[1] Numerous hemoglobin variants resulting in shortened RBC survival have been identified. Individuals with sickling hemoglobinopathies may suffer a variety of complications that require treatment in an ICU (see Chapter 90). Abnormalities in the structure of the RBC membrane, as in hereditary spherocytosis, or decreased quantities of RBC enzymes, as in G6PD deficiency, also decrease red cell survival. Hemolysis in these settings occurs primarily extravascularly. Mechanical disruption of the red cell membrane secondary to factors extrinsic to the RBC may lead to macroangiopathic hemolytic anemia, as with

turbulent flow around a prosthetic heart valve, or microangiopathic hemolytic anemia, caused by fibrin deposition in the microvasculature. The latter process is seen in consumptive disorders, including disseminated intravascular coagulation (DIC), hemolytic uremic syndrome, and thrombotic thrombocytopenic purpura.[9] In these entities, hemolysis is primarily intravascular, with characteristic schistocytes seen on the blood smear.

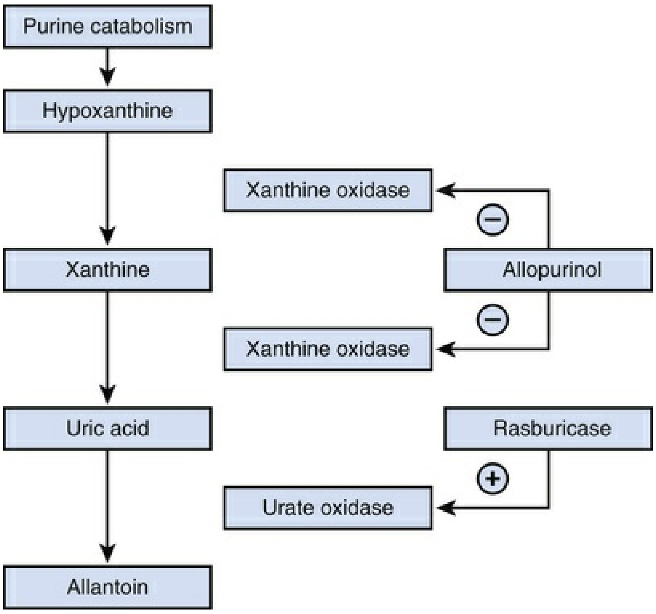

FIG. 94.1 Diagram showing purine degradation and mechanism of action of allopurinol and rasburicase. *CU*, copper; *DIC*, disseminated intravascular coagulation; *G6PD*, glucose 6-phosphate dehydrogenase; *HS*, hereditary spherocytosis; *PK*, pyruvate kinase; *PNH*, paroxysmal nocturnal hemoglobinuria.

The hemolytic processes that result from abnormal interactions between erythrocytes and the immune system are known collectively as *autoimmune hemolytic anemia* (AIHA).[1] AIHA can be classified as either primary, in which there is no identifiable systemic illness except possibly a history of a recent viral-like illness, or secondary, in which the hemolytic anemia is present in the context of another illness. AIHA has been reported as a manifestation of autoimmune disorders (eg, lupus erythematosus), immunodeficiency disorders, malignancies, specific infections, or as a drug reaction (Box 94.3).[9] AIHA also may be classified by the thermal sensitivity of the autoantibodies. The most common form is the result of warm-reactive immunoglobulin (Ig) G autoantibodies directed against RBC membrane proteins. Extravascular hemolysis occurs, with sensitized erythrocytes cleared primarily in the spleen. Cold-agglutinin disease, the second most common form of AIHA, most frequently occurs with *Mycoplasma pneumoniae* infections, but it also is associated with other infectious agents, including Epstein-Barr virus, cytomegalovirus, and mumps virus. In this disorder, IgM autoantibody binds to the RBC and fixes complement. The erythrocytes may undergo intravascular hemolysis, or they may be cleared by the reticuloendothelial system, primarily in the liver. Paroxysmal cold hemoglobinuria is a rare variant of AIHA that usually occurs following a viral illness and in which an IgG autoantibody binds at cold temperature to the P-antigen of the

erythrocyte, fixing complement (the Donath-Landsteiner antibody) and producing intravascular hemolysis. Although drug-induced autoantibodies occur uncommonly in children, they may follow exposure to some antibiotics, including penicillins and cephalosporins. Mechanisms of drug-induced hemolysis may include autoantibody formation and adsorption of the drug onto the red cell membrane, with immune complex formation with IgG or IgM.

Box 94.3

Classification of Autoimmune Hemolytic Anemia in Children

A Primary AIHA

1. Warm-reactive autoantibodies, usually IgG

2. Paroxysmal cold hemoglobinuria, usually IgG

3. Cold-agglutinin disease, usually IgM

B Secondary AIHA

1. Systemic autoimmune disease (eg, lupus)

2. Malignancy (Hodgkin and non-Hodgkin lymphoma)

3. Immunodeficiency

4. Infection (*Mycoplasma*, viruses)

5. Drug induced

Patients with AIHA usually present with pallor, jaundice, and splenomegaly on physical examination. The reticulocyte count is generally elevated, although initially it may be low or normal. The direct antiglobulin test (Coombs test) demonstrates the presence of antibodies or complement on the red cells. The indirect antiglobulin test measures the presence of unbound antierythrocyte antibodies in the patient's serum.

Therapy depends on the type of AIHA and the severity of clinical symptoms. Profound anemia, usually with a hemoglobin level of less than 5 g/dL, may result in cardiovascular compromise and requires erythrocyte transfusion to increase O_2-carrying capacity. The presence of autoantibodies often makes cross-matching blood difficult, and the patient may require transfusion with "least incompatible" blood. Significant hemolytic transfusion reactions are infrequent. However, severe hemolysis occurs on rare occasions, with hemoglobinemia and hemoglobinuria resulting in renal failure. Therefore transfusions should be started at a slow rate, and both plasma and urine samples should be checked regularly for free hemoglobin. Patients with cold-reactive antibodies should be kept warm, and a blood warmer should be used for the transfused blood. Even in the absence of transfusion, significant intravascular hemolysis may occur in patients with cold-reactive

antibodies. Maintaining good renal blood flow and careful monitoring of urine output in this setting may help obviate renal injury. Corticosteroids appear to slow the hemolytic process, particularly in patients with IgG autoantibodies, in whom this drug class appears to inhibit Fc receptor-mediated clearance of sensitized erythrocytes. The usual dosage is 1 to 2 mg/kg methylprednisolone administered intravenously every 6 hours until the patient is clinically stable. The patient then can be switched to oral prednisone (2 mg/kg/day for 2 to 4 weeks, followed by a slow taper over 1 to 3 months).

Corticosteroids may also be effective in cold agglutinin disease, although the response is less predictable. High-dose intravenous γ-globulin (IVIG, 1 g/kg/day for 5 days) produces response in approximately one-third of patients with warm-reactive disease. Plasmapheresis and plasma exchange may be beneficial, particularly in patients with IgM autoantibodies. The overall prognosis for children with AIHA is good. Cold-reactive AIHA generally resolves completely. Some patients with warm-reactive antibodies have a chronic course, marked by remissions and exacerbations.

Thrombocytopenia

Thrombocytopenia may be secondary to either decreased platelet production or increased platelet destruction. Decreased platelet production may result from primary bone marrow failure states or from bone marrow infiltration by malignant cells as in leukemia, lymphoma, and metastatic solid tumors. Bone marrow suppression, a common side effect of antineoplastic therapy including both chemotherapy and radiotherapy, frequently leads to periods of thrombocytopenia. Thrombocytopenia or platelet dysfunction may result in bleeding, usually involving the skin and mucous membranes. Clinical manifestations include petechiae and purpura, epistaxis, gastrointestinal bleeding, hematuria, and menorrhagia. Intracranial hemorrhage is an infrequent manifestation of thrombocytopenia.

Indications for platelet transfusion in these settings vary with the underlying cause of thrombocytopenia and the patient's clinical status. Patients with primary bone marrow failure, who likely will experience prolonged thrombocytopenia, generally receive transfusions only for active bleeding because of the risk of alloimmunization. In addition, exposure to multiple platelet donors may jeopardize the success of bone marrow transplantation by increasing the risk of graft rejection. The threshold for transfusion may need to be higher in patients with sepsis, decreased humoral coagulants, or other risk factors. In the perioperative setting, platelet counts should be maintained at higher than 50,000/dL and greater than 100,000/dL for neurologic or ophthalmologic surgery. Use of ABO-compatible donors and leukoreduction diminishes the risk of platelet alloimmunization. Single-donor apheresis units reduce donor exposure compared with pooled platelet concentrates, but whether such usage reduces the incidence of platelet alloimmunization remains unclear.

Immune Thrombocytopenia

Immune platelet destruction may be caused by autoantibodies, drug-dependent antibodies, or alloantibodies. Alloantibodies result from exposure to polymorphic

epitopes expressed on foreign platelets to which the patient has been exposed (see the previous section). Drug-induced thrombocytopenia may be suggested by the patient's medication history. Laboratory tests for specific drug-associated antiplatelet antibodies are available.

In immune thrombocytopenia purpura (ITP), autoantibodies to platelets may be associated with other autoimmune disorders, immune deficiency states, or after viral illness or immunization. The incidence of childhood ITP was found to range from 5 to 7 per 100,000 per year, with 25% of the children subsequently developing chronic ITP.[10] Frequently no predisposing condition is identified (idiopathic thrombocytopenia purpura). Regardless of cause, the reticuloendothelial system removes antibody-coated platelets, with the bulk of the destruction occurring in the spleen. These children typically present with petechiae, purpura, bleeding from mucous membranes, and isolated thrombocytopenia. The bone marrow responds with increased platelet production. The rapid turnover in platelets results in younger, somewhat larger platelets entering the blood. Hence, serious bleeding rarely occurs because of the increased effectiveness of platelets. Low admission mean platelet volume value (<8 μL) and a history of viral prodrome have been found to be independent prognostic variables that predicted durable remission.

The primary goal of therapy in children with ITP is to limit bleeding, especially from the central nervous system. Therapy does not appear to affect the natural history of the illness. There is no consensus regarding the management of acute ITP, and the need for intervention in the absence of significant hemorrhage remains the subject of debate. Intracranial hemorrhage remains rare, and there are no data that treatment actually reduces the incidence of intracranial hemorrhage. Therapy is directed at slowing clearance of sensitized thrombocytes in the spleen and reducing antibody production. Initial medical management usually involves the use of corticosteroids (methylprednisolone 30 mg/kg/dose × 3 doses) or IVIG (1 g/kg/dose × 2) resulting in increased platelet counts within 48 hours.[11] Meta-analysis of randomized controlled trials (RCTs) comparing high-dose to low-dose IVIG showed no difference in outcomes, with significantly reduced risk of side effects with low-dose IVIG (total dose less than 2 g/kg).[12] Bone marrow evaluation to rule out malignancy before corticosteroid therapy should occur. Infusion of anti-Rh(D) immunoglobulin (50 to 75 μg/kg) for individuals who have Rh(D)-positive RBCs prolongs survival of antibody-coated platelets in patients with ITP but should be avoided in patients who present with anemia. As with IVIG, the major mechanism appears to include blockage of Fc receptors on reticuloendothelial cells. Use of these agents usually halts bleeding and raises platelet counts to safe levels within a few days, although evidence indicating their influence on the course of the disease remains lacking.

Intracranial hemorrhage, a devastating but rare complication of ITP, requires immediate intervention. Consequently, patients presenting with headaches, persistent vomiting, or neurologic symptoms require an emergent computed tomography (CT) scan of the head. Therapy for intracranial hemorrhage usually includes IVIG, corticosteroids, and emergency splenectomy.[13] Platelet transfusions in ITP rarely result in an increase in the platelet count because of rapid consumption of transfused platelets. Nevertheless, intermittent (2 to 4 IU/m^2 every 6 to 8 hours) or continuous (0.5 to 1 IU/m^2/hr) platelet transfusions have been administered for life-threatening hemorrhage, with decreases in bleeding reported. Plasmapheresis may

be beneficial in patients who do not respond to these interventions. A splenectomy should be performed if a craniotomy is required, to maximize the perioperative platelet count.[14]

Nonimmune Thrombocytopenia

DIC occurs when generalized activation of the plasma coagulation pathways occurs within small blood vessels with formation of fibrin and depletion of circulating levels of clotting factors and platelets. DIC usually follows a systemic insult, most often sepsis or shock. Treatment should be directed to the underlying cause. Hemorrhage frequently occurs at platelet counts greater than 10,000/μL because of concomitant depletion of clotting factors. Control of bleeding may necessitate platelet and plasma transfusions. DIC had been thought to be the etiology of much of the multiorgan system failure in ICU patients, with formation of a large number of microthrombotic foci leading to organ microcirculation failure and subsequent failure of the organ itself (see Chapter 112). More recently, some studies have suggested that vascular endothelial damage induced by humoral mediators is the primary cause of thrombocytopenic multiorgan system failure. In these instances, thrombocytopenia may be a marker of poor prognosis rather than a cause of ICU mortality.

Increased platelet consumption with resultant thrombocytopenia occurs in diseases associated with extensive vascular endothelial damage, including hemolytic uremic syndrome and thrombotic thrombocytopenic purpura. Aggregates of activated platelets become trapped in small blood vessels, causing a microangiopathic hemolytic anemia. Schistocytes usually are present on the peripheral blood smear. Platelet transfusions should be given only for life-threatening bleeding because they may worsen the thrombotic process.[15]

Thrombocytopenia caused by splenic sequestration develops in individuals with massive splenomegaly. The etiology of splenomegaly includes infectious, infiltrative, neoplastic, obstructive, and hemolytic causes. The Kasabach-Merritt syndrome is an association of a giant hemangioma with localized intravascular coagulation causing thrombocytopenia and hypofibrinogenemia. Rare congenital thrombocytopenic syndromes include congenital amegakaryocytic thrombocytopenia, thrombocytopenia-absent radius, and Wiskott-Aldrich syndrome.

Bleeding in Uremia

Hemorrhagic manifestations in patients with renal failure are characterized by purpura and bleeding from mucous membranes and puncture sites. Gastrointestinal bleeding may contribute to morbidity and mortality in patients with end-stage renal disease. Concurrent hypertension increases the risk of subdural hematoma. The hemostatic defect in uremia is multifactorial, resulting in part from altered metabolism of platelets and vascular endothelial cells and from abnormal interactions between platelets and vascular endothelium.[16]

When uremia is present, clinical bleeding may be increased relative to the degree of thrombocytopenia resulting from secondary platelet dysfunction. Intravenous administration of desmopressin acetate (0.3 μg/kg over 30 minutes) improves platelet dysfunction caused by uremia within 1 hour with an effect for 4 to 8 hours.[17]

Tachyphylaxis may occur after two to three doses. Intravenous or transdermal conjugated estrogens or oral estrogens cause slower but more sustained improvements in bleeding time.[18] Dialysis improves platelet function through reduction of azotemia.

When severe anemia is present, platelets travel closer to the blood midstream and are less likely to interact with the vascular endothelium. In addition, RBCs exert metabolic effects on platelets by enhancing adenosine diphosphate and thromboxane A2 release. Therefore use of red cell transfusions or erythropoietin to increase the hematocrit to 30% helps to correct the bleeding time.[19] Further increase in hematocrit increases the risk of thrombosis, particularly of arteriovenous shunts and the extracorporeal hemodialysis circuit.

Oncologic Emergencies

Tumor Lysis Syndrome

Tumor lysis syndrome (TLS) results from the death of tumor cells resulting in the rapid extravasation of intracellular contents into the blood.[20] The release of intracellular contents may cause metabolic derangements and produce end-organ damage. Careful monitoring and rigorous attention to organ function may help to obviate the majority of complications from this syndrome. Although the lysis of malignant cells usually begins after the institution of chemotherapy, spontaneous TLS can occur.[21] Important considerations in TLS include the level of tumor burden and the sensitivity of the cells to the antitumor agents.[22] In children, hematologic malignancies such as acute lymphoblastic leukemia (ALL), acute myelogenous leukemia (AML), and Burkitt lymphoma account for the majority of cases of TLS.[23] TLS usually occurs with new-onset disease, preexisting renal dysfunction, in the setting of nephrotoxic drugs, and with dehydration. Conventionally, the diagnosis of TLS requires some combination of hyperkalemia, hyperphosphatemia, hyperuricemia, and hypocalcemia in the face of a tumor; however, no definitive classification or grading system exists. Although some differentiate between laboratory and clinical TLS, the value of published classifications has not been established.

On cell lysis, tumor cells release normal or supranormal quantities of many intracellular contents that pour into the circulation on cell death including potassium, nucleic acids, inorganic phosphates, and proteins.[20] The metabolism of nucleic acids results in the production of uric acid. With high tumor burden and highly effective chemotherapy, a massive release of these chemicals may overwhelm normal homeostatic mechanisms, threatening the patient with hyperkalemia, hyperphosphatemia, hyperuricemia, hypocalcemia, and end-organ damage.

Hyperkalemia can acutely threaten cardiovascular status by altering cardiac rhythm. Levels of potassium greater than 6.5 to 7 mmol/L may lead to widening of the QRS complex and peaked T waves that can progress to disorganized ventricular rhythms and severe cardiac dysfunction. Other symptoms include irritability, fatigue, muscle weakness and cramps, paresthesias, nausea, emesis, and diarrhea. Hyperkalemia must be addressed emergently.

Phosphate released during TLS avidly binds to calcium, depleting serum calcium levels. The resultant calcium phosphate may precipitate in the renal tubules,

exacerbating renal dysfunction, and producing fatigue, lethargy, weakness, nausea, and emesis. Hypocalcemia may also result in muscle cramps, tetany, seizures, and dysrhythmias. Counterintuitively, low levels of calcium must be addressed by treating the elevated phosphate rather than by administering intravenous calcium.

Uric acid, the final product of purine nucleotide metabolism, is excreted in the urine but has low solubility, especially in acidic urine. Production of uric acid depends on the enzyme xanthine oxidase. Hyperuricemia may injure renal tubules through various mechanisms including deposition of urate crystals in renal tubules causing microobstruction, altering kidney hemodynamics through vasoconstriction, and possible direct toxic effects on the nephron through various mechanisms, especially in the context of dehydration and administration of nephrotoxic medications.[24,25] Increasing serum uric acid levels have been associated with increasing risk for TLS.

Uremia may also occur in patients at risk for TLS either from TLS itself, from preexisting renal injury, or from a combination of these factors. In TLS, the most common cause of renal injury is precipitation of uric acid crystals in the renal tubule, but it can be due to calcium phosphate or xanthine crystals, nephrotoxic drugs, tumor infiltration, or obstruction and infection.[26]

The bedrock of therapy is volume expansion to assure adequate end-organ perfusion and a robust urine flow rate. Sometimes, in order to protect end organs, additional medications are needed to alter uric acid production or to more rapidly bind or eliminate abnormal electrolytes.

Hyperkalemia is a medical emergency, especially when the level exceeds 6.5 to 7 mEq/dL. Therapy includes oral or rectal cation exchange resins, intravenous calcium (gluconate or chloride) to antagonize the action of K^+ on the cardiac myocyte, and sodium bicarbonate to correct acidosis and increase the gradient of K^+ into the cells. Insulin and glucose encourage the movement of K^+ into cells. Diuretic therapy or dialysis may be used to help the excretion of K^+ (see also Chapter 78).

Treatment of hyperuricemia is accomplished by optimizing elimination through alkalization of the urine and decreasing uric acid production through allopurinol or urate oxidase (rasburicase). The solubility of uric acid is highly pH dependent. With an increase in pH from 5 to 7, urine concentrations of uric acid increase from 15 mg/dL to 200 mg/dL.

Allopurinol, a xanthine analogue, inhibits the conversion of xanthine and hypoxanthine to uric acid by competitively blocking the enzyme xanthine oxidase and thus reduces the incidence of obstructive uropathy caused by uric acid.[27,28] Allopurinol cannot, however, lower elevated uric acid levels that may precede therapy, and inhibition of xanthine oxidase may increase the levels of xanthine, which may also produce renal tubular damage.

Hyperuricemia that persists after volume expansion and allopurinol or that is dangerously elevated on presentation requires aggressive therapy. Urate oxidase, a nonhuman lytic enzyme, cleaves uric acid to allantoin, carbon dioxide, and hydrogen peroxide, which are highly water soluble and easily eliminated. Rasburicase, a recombinant urate oxidase, is very expensive but highly effective at reducing uric acid levels rapidly. Though still recommended for use in high-risk patients, a Cochrane Review in 2014 found that in the seven pediatric trials to date, it was unclear whether urate oxidase reduces clinical tumor lysis, renal failure, or mortality. Rasburicase is contraindicated in patients with a known G6PD deficiency

(certain patients of African-American, Mediterranean, or Southeast Asian descent) and in pregnant or lactating females.[29]

Hyperphosphatemia results in an initial increase in urinary excretion and decreasing tubular reabsorption, but this mechanism is limited. Excretion of phosphates is impaired by renal injury. Hyperphosphatemia may result in precipitation of calcium phosphate crystals, which can cause or worsen renal dysfunction. Crystallization appears to increase when the calcium phosphate multiple exceeds 70 and when the urine has been alkalinized; therefore attention should be given to stopping alkalinized intravenous fluids for patients with hyperphosphatemia.

Hyperleukocytosis

Hyperleukocytosis, arbitrarily defined as a white blood cell (WBC) count greater than 100,000/μL, is seen in 5% to 20% of children diagnosed with leukemia, most often in patients with ALL.[30] Hyperleukocytosis causing symptomatic leukostasis usually occurs with WBC counts greater than 200,000/μL in AML, greater than 300,000/μL in ALL, and greater than 600,000/μL in chronic myeloid leukemia.[31] Leukostasis seems to happen at lower WBCs in AML because myeloblasts and monoblasts tend to be larger and more rigid than lymphoblasts and granulocytes and are more likely to obstruct vessels.

The viscosity of the blood is dependent on the leukocyte and erythrocyte volumes as well as the deformability of the cells.[32] Substantial increases in WBC counts produce aggregates of leukocytes, which may obstruct small blood vessels. Leukostasis results in local hypoxia, and invasion of the blood vessels by leukemic cells can produce organ and vascular damage or hemorrhage. Leukemic cells' variable expression of adhesion molecules and cytokines, such as interleukin-1 and tumor necrosis factor-alpha, may explain the variability of WBC and clinical presentation of patients with leukostasis.[30]

Children with hyperleukocytosis have higher rates of morbidity and mortality than other children with leukemia. Children with AML and hyperleukocytosis have a higher risk of early morbidity and mortality than patients with nonhyperleukocytosis AML or ALL and hyperleukocytosis, but the true incidence of these complications is not well elucidated.[33] Based mostly on adult data, there is a 20% to 40% mortality associated with symptomatic leukostasis within the first week of presentation. Hyperleukocytosis most frequently causes neurologic leukostasis, pulmonary leukostasis, and tumor lysis syndrome.

Signs and symptoms of neurologic leukostasis may include headache, altered mental status, visual disturbances, or seizures. The most concerning neurologic complication is an intracranial hemorrhage, which typically is limited to the white matter. The risk for intracerebral hemorrhage can persist even after reduction of the WBC count. Clinicians should consider urgent neuroimaging with any changes in a patient's neurologic status with judicious use of intravenous contrast. Central nervous system hemorrhage with high WBC counts occurs in 5% to 33% of patients with AML and hyperleukocytosis, usually correlating with the degree of hyperleukocytosis.[32]

Respiratory symptoms found with pulmonary leukostasis may include dyspnea, hypoxemia, respiratory failure, and acute respiratory distress syndrome. Arterial

measurement of oxygenation should be interpreted with caution because pseudohypoxemia from so-called leukocyte larceny can occur even with samples immediately placed on ice. Pulse oximetry may be a more reliable measure of oxygenation. Chest radiograph findings of pulmonary leukostasis may be normal or reveal diffuse interstitial infiltrates. Immediate cytoreduction is indicated when excessive O_2 metabolism of leukocytes causes tissue hypoxemia. Elevated serum lactate levels have been described as an early sign of microcirculatory failure.[30]

Therapy for hyperleukocytosis has not undergone rigorous analysis. Diuretic therapy and packed red cell transfusion both increase viscosity and are best avoided. Concurrent thrombocytopenia and hyperleukocytosis increase risk of death from bleeding complications. Aggressive therapy with fresh frozen plasma and vitamin K to correct coagulopathy and maintenance of platelet count greater than 20,000/μL are critical.[30] Hydration, alkalinization, and allopurinol have been used in patients with WBC counts higher than 100,000/μL.[31] More aggressive therapies must be considered for symptomatic patients, especially those with laboratory evidence of hypoxia or ischemia, or in certain patients depending on malignancy type and WBC count. Exchange transfusion, leukapheresis, or chemotherapy can be used to rapidly lower WBC. No randomized trials of cytoreduction have been performed, and although a reduced incidence of electrolyte abnormalities has been shown, no improvement in pulmonary status, central nervous system outcome, or mortality has been demonstrated.[34] Complications of leukapheresis include difficulty with vascular access, rapid rebound of WBC count, and the need for anticoagulation. Cytoreduction by leukapheresis, exchange transfusion, or other methods may modulate cell-cycle distribution and nucleoside transporters in leukemic cells by increasing the fraction of the S-phase. No beneficial role has been demonstrated for use of corticosteroids or emergency cranial radiation.[32] Leukapheresis should never be undertaken in a patient with suspected acute promyelocytic leukemia due to hemorrhagic complications.

Spinal Cord Compression

Compression of the spinal cord by malignancy occurs uncommonly but still represents an important cause of morbidity in children, affecting between 2.7% to 5% of children with cancer. Most frequently, compression occurs as metastatic disease spreads rather than as primary spinal cord tumors themselves. Ewing sarcoma, neuroblastoma, and primitive neuroectodermal tumors appear to be the most frequent diagnoses, although compression may be found with lymphoma, nephroblastoma, and germ cell tumors.[35]

Most cord compression results from epidural compression due to extension of paravertebral tumor through the intervertebral foramina or, less commonly, extension of the tumor in the vertebral column. Compression of the vertebral venous plexus by epidural tumor causes vasogenic cord ischemia, edema, venous hemorrhage, and myelin loss.[36] Spinal cord compression usually localizes to the dorsal and lumbosacral regions (42% each). Patients frequently develop back pain, motor dysfunction, sphincter abnormalities, and alteration in sensation. Such findings represent harbingers of potential permanent loss of neurologic function, necessitating emergent evaluation including magnetic resonance imaging.

Confirmation of tumor compression of the spinal cord requires emergent medical

action. Treatment requires 1 mg/kg dexamethasone intravenously over 30 minutes and next mandates a decision between immediate surgical decompression, radiation therapy, or chemotherapy. This decision is influenced by a number of factors, including the presence of a histologic diagnosis, likelihood of response to chemotherapy or radiotherapy, as well as degree and rate of progression of neurologic deficit. Although controversy exists, decompressive laminectomy is indicated for tumors without a diagnosis, patients with small cell tumors with rapid neurologic deterioration or complete loss of motor function, and sarcoma, with the exception of osteogenic sarcoma.[35] Laminectomy in children often leads to scoliosis, kyphosis, and anterior subluxation. Consequently, the decision must be made with this issue in mind, as laminectomy patients often require subsequent treatment for orthopedic sequelae of the initial surgery. Among children with complete sensory and motor loss below the level of spinal cord compression, 30% to 60% of treated children experience neurologic recovery.[36]

Acute Airway Compromise in Anterior Mediastinal Tumors

Childhood mediastinal masses pose difficult diagnostic and therapeutic challenges. Such masses often produce few symptoms until they have occluded a substantial portion of the trachea or main stem bronchi or the superior vena cava. Complete airway occlusion in these children represents a potentially fatal complication, a risk that increases at the time of sedation for diagnostic procedures. An estimated 9% to 15% of pediatric patients with anterior mediastinal masses and airway obstruction have been reported to develop life-threatening complications with anesthesia.[37-39] Since the 1990s, increased awareness of the potential for airway or cardiovascular collapse in pediatric patients with anterior mediastinal masses has led to improved management. Major airway complications are now more likely to occur in the postanesthetic period.[40] Superior vena cava syndrome, left atrial compression, and pericardial effusion may lead to a state of fixed cardiac output.

Mediastinal masses are classified by their anatomic compartment, and anterior mediastinal masses represent 46% of all such masses in children.[41] The most common tumors found in the anterior mediastinal compartment include hematologic malignancies: T-cell lymphoblastic leukemia, Hodgkin disease, and T-cell lymphoblastic non-Hodgkin lymphoma.[42,43] Children with an anterior mediastinal mass often present with nonspecific findings including orthopnea, dyspnea, cough, pleural effusion, wheezing, superior vena cava (SVC) syndrome, pain, and stridor.[44] Mediastinal masses are far more common in older children and teenagers than in children younger than 5 years. Barking cough and stridor in an older child or teenager rarely occur with croup and therefore require further investigation.

Important risk factors for airway compromise include computed tomography findings of more than 50% decrease in a cross-sectional area of the trachea, peak expiratory flow less than 50% of predicted value, anterior mediastinal mass, tracheal compression, main stem bronchus compression, larger median mediastinal mass ratio, lymphoma, vena cava syndrome, pericardial effusion, pleural effusion, history of recurrent chest infections, stridor, orthopnea, cough, wheeze, and shortness of breath.[37,38] The predictive value of these risk factors remains controversial, however. Unfortunately, compression at the level of the carina or bronchi may contribute

appreciably to respiratory compromise, even in patients with a cross-sectional area above 50% of predicted.[43] A computed tomography scan will provide evidence of airway compression at a tracheal or bronchial level as well as the existence of exacerbating factors such as pleural effusion that may limit a patient's physiologic reserve.

The preoperative evaluation of patients with critical airway from compression by an anterior mediastinal mass should include an experienced multidisciplinary pediatric team made up of an oncologist, anesthesiologist, interventional radiologist, surgeon, and intensivist. Computed tomography provides the most useful, rapid step in the assessment for airway compromise; unfortunately, severe or rapid progressive symptoms may preclude lying supine for the scan (Fig. 94.2). In such cases, the risks and benefits of performing a diagnostic procedure under local anesthesia with ultrasound guidance, beginning preoperative treatment prior to pathologic diagnosis, or proceeding with general anesthesia need to be discussed by the team and with the family. Empiric treatment is controversial because it can distort the histopathologic appearance and hinder a definitive diagnosis. However, in one study an accurate diagnosis was made in 95% of patients receiving corticosteroids prior to biopsy.[42] Bone marrow or lymph node biopsy and pleural fluid analysis may be helpful in patients who are not unstable. Complete blood count and α-fetoprotein, β-human chorionic gonadotropin, and lactate dehydrogenase levels should be obtained. Image-guided needle biopsy performed under local anesthesia for mediastinal mass or lymph node by a skilled interventional radiologist remains the diagnostic test of choice.[43]

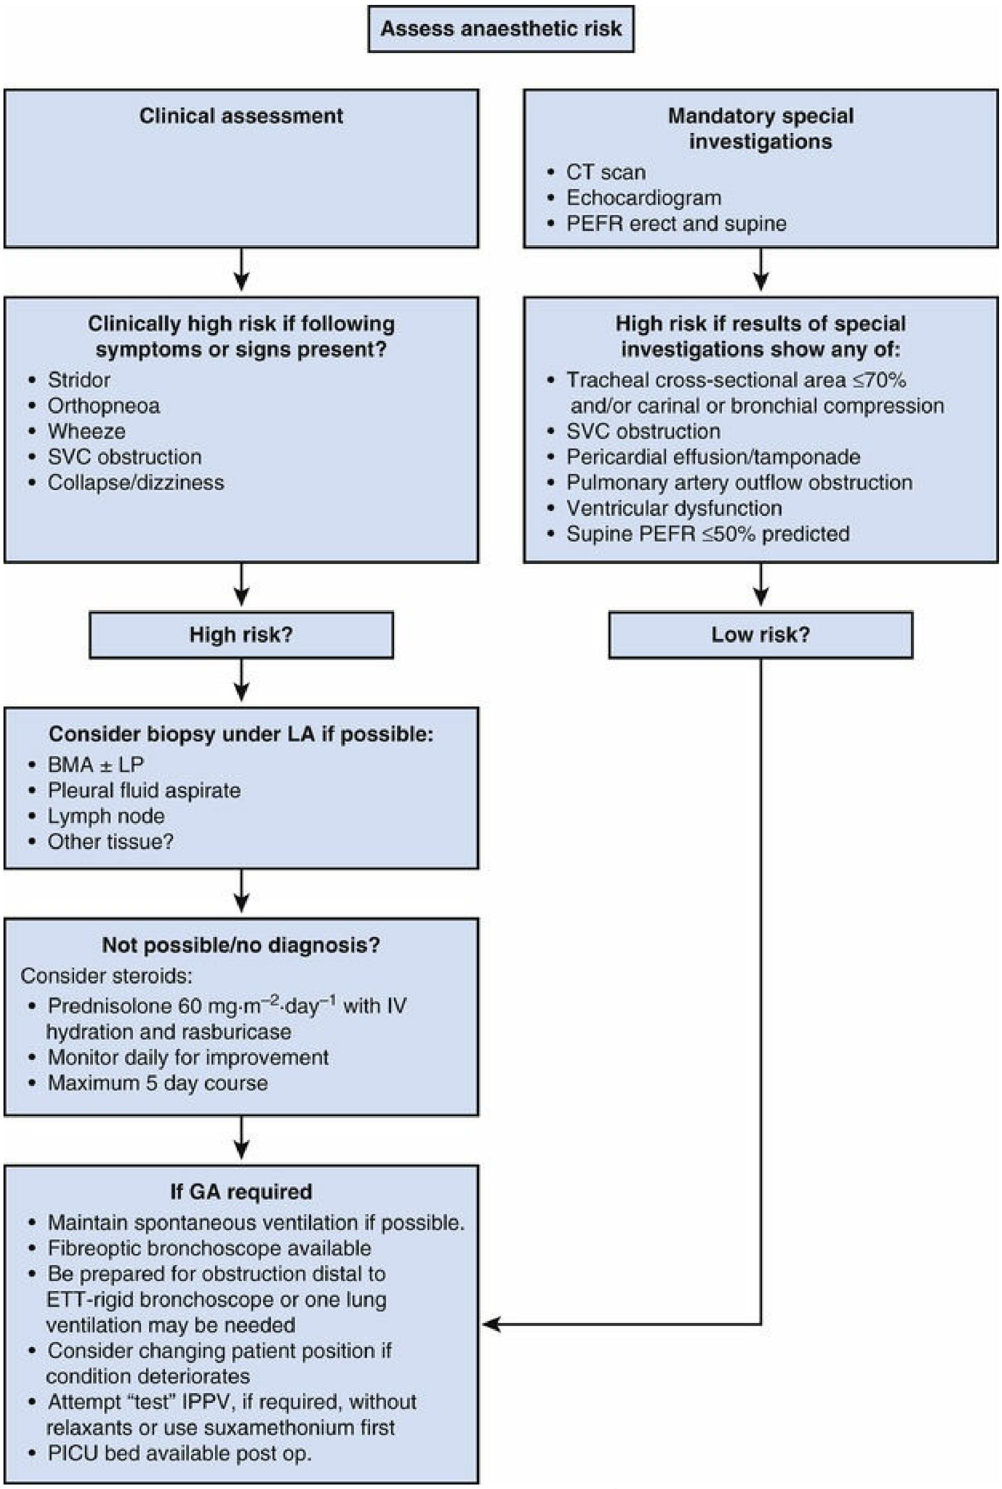

FIG. 94.2 Preoperative anesthetic guidelines for a child with a mediastinal mass. (From Hack HA, Wright NB, Wynn RF. The anaesthetic management of children with anterior mediastinal masses. Anaesthesia 2008;63:837-846; with permission.)

Superior Vena Cava Syndrome

SVC syndrome encompasses the signs and symptoms related to compression or obstruction of the SVC, which in childhood most commonly results from anterior mediastinal mass, middle mediastinal lymph nodes, or occlusion of the SVC itself.

SVC obstruction may be accompanied by compression of other mediastinal structures, large airways, pulmonary vessels, and aorta. SVC syndrome is most often caused by lymphoid malignancy, including non-Hodgkin lymphoma, acute lymphocytic leukemia, and Hodgkin disease. In addition to malignancies, indwelling catheters, previous cardiac surgery, previous extracorporeal life support, right-sided congenital diaphragmatic hernia, and ventriculoperitoneal shunts are other causes of SVC syndrome in pediatric patients.

In children, respiratory symptoms usually predominate; air hunger, dyspnea, wheezing, and anxiety occur, particularly with position change. The gradual development of SVC syndrome may manifest with periorbital edema, conjunctival suffusion, facial swelling, dizziness, syncope, and cough. SVC syndrome may occur in conjunction with spinal cord compression (Rubin syndrome), where significant venous obstruction usually develops before the spinal cord compression. Patients with SVC syndrome and back pain should be evaluated with magnetic resonance imaging of the vertebral spine when their condition is stable.

Evaluation of an anterior mediastinal mass was described previously. As in airway compression, SVC syndrome places a patient at significant risk for anesthetic complications during diagnostic procedures. CT should be pursued without sedation and may require prone positioning because compression of the great vessels may occur despite a patent airway, resulting in profound hypoxia and reduced cardiac output. In addition, echocardiography can evaluate cardiac motility and the degree of venous return. Diagnosis should be established with the least invasive means available, but empiric anticancer therapy may be required if no histologic sample can be obtained safely. Tissue for definitive diagnosis should be obtained as soon as the patient's clinical status allows in order to decrease the likelihood that empiric therapy will permanently obscure the diagnosis.

Hemophagocytic Lymphohistiocytosis

Hemophagocytic lymphohistiocytosis (HLH) describes a syndrome of conditions rather than a specific disease entity that is marked by hyperinflammation resulting from riotously elevated circulating cytokines.[45] HLH represents an emergency because it shares many clinical features with the systemic inflammatory response syndrome (SIRS) or sepsis syndrome. These similarities make the diagnosis difficult; however, identifying HLH results in a much different treatment algorithm.[46] Inadequately treated HLH results in very poor outcomes. Classically, HLH is thought to occur as a consequence of acquired or inherited defects in cytotoxic activity, but emerging data suggest that HLH should be viewed as a single syndrome with a continuum of risk factors.[47] Generally, these defects diminish elimination of cellular targets and impair down-regulation of the immune response.[45] HLH arises from abnormalities involving the process by which cytotoxic vesicles migrate to contact, attach, fuse, and release their contents with a target cell. Familial HLH is usually an autosomal recessive condition and is caused by one of several mutations in the natural killer (NK)/T-cell cytotoxic pathway.[48] Perforin is a cytotoxic protein stored in secretory granules of cytotoxic cells, and defects in this protein account for 50% of all familial HLH cases in North America.[49] Familial HLH is associated with and can be the initial presentation of an immunodeficiency syndrome such as Chediak-Higashi syndrome, Griscelli syndrome, and X-linked

lymphoproliferative syndrome.

Acquired HLH most frequently occurs in the setting of infections, malignancy, or rheumatologic conditions; however, the mechanism of impairment of natural killer cells and cytotoxic lymphocytes in secondary HLH remains unclear but occurs in all age groups.[45] Less common associations include Kawasaki disease, metabolic diseases such as lysinuria protein intolerance, multiple sulfatase deficiency, and Wolman disease. *Macrophage activation syndrome* is a term commonly used to describe HLH in the setting of an underlying autoimmune disorder, most commonly rheumatoid arthritis.

Patients typically present with signs and symptoms of systemic infection or SIRS including prolonged fever (usually unresponsive to antibiotics), hepatosplenomegaly, and cytopenias. In some patients, neurologic symptoms, seizures, and cranial nerve palsies may occur. Because HLH often mimics other conditions, a high index of suspicion remains paramount. Fortunately, diagnostic guidelines exist (Box 94.4), but each clinical situation must be considered carefully because of the substantial overlap with severe sepsis, SIRS, and multiple organ dysfunction syndromes.

Box 94.4

Diagnostic Criteria for Hemophagocytic Lymphohistiocytosis

Familial Disease/Known Genetic Defect

Clinical and Laboratory Criteria (Five of Eight Criteria)

1. Fever

2. Splenomegaly

3. Cytopenia ≥2 cell lines

4. Hemoglobin <90 g/L (below 4 weeks <120 μg/L)

5. Platelets $<100 \times 10^9$/L

6. Neutrophils $<1 \times 10^9$/L

7. Hypertriglyceridemia or hypofibrinogenemia

a. Fasting triglycerides >3 mmol/L

b. Fibrinogen <1.5 g/L

8. Ferritin >500 lg/L

9. sCD25 = >2400 U/mL

. Decreased or absent natural killer cell activity

. Hemophagocytosis in bone marrow, CSF, or lymph nodes

Laboratory studies often aid in diagnosis but may not be routinely obtained in patients who may have provisional diagnoses such as severe sepsis. Diagnostic criteria require a ferritin level higher than 500 ng/mL, but the levels are usually much higher, exceeding 10,000, unlike in sepsis where serum ferritin is elevated but appears to be generally below 2000. Serum triglycerides often are elevated. Soluble interleukin-2 receptor (sCD 25) and soluble Fas (CD178) are elevated. Although helpful in making the diagnosis of HLH, hemophagocytosis may be absent early in the disease, can be missed on bone marrow aspirates, and is a nonspecific finding.

Treatment depends on whether HLH is genetic or acquired. Initial treatment is meant to suppress hyperinflammation using immunosuppressive and cytostatic treatment with corticosteroids, cyclosporine A, or etoposide.[45] Identification of infection or malignancy should prompt immediate treatment of the underlying disease. Evidence of macrophage activation syndrome should prompt rheumatologic consultation.

Patients with primary HLH or underlying immune deficiency may require stem cell transplantation.

Anthracycline-Induced Cardiogenic Shock

The anthracyclines daunorubicin, doxorubicin, epirubicin, mitoxantrone, and idarubicin are used for chemotherapy for a wide variety of solid tumor and hematopoietic malignancies of childhood. Unfortunately, 15% of all pediatric cardiomyopathies occur in patients treated for childhood or adolescent malignancies.[50] In one prospective study, after anthracycline treatment, 5% of the children developed heart failure and 19% presented abnormal left ventricular function.[51] Shortening fractions declined proportionately to cumulative doses. Furthermore, differential susceptibility to cardiotoxicity became apparent early in treatment. Hence, patients at high risk for important anthracycline cardiotoxicity may be identifiable early in treatment by regular echocardiography. Pediatric age and female gender are known risk factors for anthracycline cardiotoxicity.

Anthracycline-induced acute myocardial injury is a rare form of cardiotoxicity that may occur immediately after a single dose or after a course of anthracycline therapy, with clinical symptoms usually occurring within a week of treatment.[52] Acute cardiotoxicity ranges from relatively benign arrhythmias to serious conditions such as fatal ventricular arrhythmias, myocardial ischemia/infarction, congestive heart failure, and cardiomyopathy.

The pathophysiology of anthracycline-induced cardiotoxicity may include free-radical–mediated myocyte damage, adrenergic dysfunction, intracellular calcium overload, and release of cardiotoxic cytokines. The myocardium appears susceptible to free radical damage from low levels of superoxide dismutase, catalase, and glutathione peroxidase activity. Cardiac mitochondria contain a unique enzyme (reduced nicotinamide adenine dinucleotide dehydrogenase) in their inner membrane that reduces anthracyclines to their semiquinones, producing severe oxidative damage to mitochondrial DNA, reductions in cellular energy production,

and myocyte apoptosis.

Prevention of cardiotoxicity remains the ultimate goal. There is evidence that dexrazoxane reduces the cardiotoxicity associated with some anthracyclines without affecting the efficacy of anthracycline therapy.[53] The antioxidant CoQ10 is an integral component of the mitochondrial respiratory chain and has successfully been used in the treatment of cardiac failure.

The outcome of anthracycline-induced cardiogenic shock during chemotherapy remains poor. The myocardium has limited regeneration ability. The mortality rate related to anthracycline-associated heart failure is substantial; heart transplantation is often the only option for long-term survival.[5] Supportive treatment including mechanical support (eg, extracorporeal life support or ventricular assist devices) may stabilize patients while decisions about longer term care can be made.[54]

Posterior Reversible Encephalopathy

Posterior reversible encephalopathy syndrome (PRES) is a clinicoradiographic syndrome that classically presents with clinical signs and symptoms of headache, visual acuity disturbances, abrupt changes in mental status, and seizures with neuroimaging showing posterior white matter edema. The reversible posterior leukoencephalopathy syndrome was initially characterized by Hinchey and colleagues in 1996 in a case series that included patients aged 15 to 62 and was closely associated with hypertensive encephalopathy, preeclampsia/eclampsia, cyclosporine A neurotoxicity, and uremic encephalopathy.[55] As more cases were reported and neuroimaging improved, the name PRES was introduced in 1999 by Casey as a better description of the syndrome because the radiographic lesions were not felt to be consistent with a leukoencephalopathy.[56] Since the 1990s, PRES has become more clinically recognized in pediatric populations, especially in those pediatric populations who are exposed to immunomodulatory or cytotoxic therapy.[57] Although the exact incidence of PRES is unknown, in the context of tacrolimus or CSA used after solid organ transplant, PRES developed in 1% to 6% of all recipients. The exact precipitating factor for PRES is unknown but it is felt that the syndrome is associated with a disorder of cerebrovascular autoregulation likely from multiple etiologies. It is believed that the severe hypertension or other causes of PRES disrupt cerebrovascular autoregulation with a resulting leakage of fluid into brain parenchyma. Compared to the carotid system, the vertebrobasilar system has fewer adrenergic innervations, which may make it more prone to disruption of its autoregulation. This may explain the predominance of lesions in the posterior cerebral area seen in PRES. Although lesions can be seen in the cortex, the cortex is thought to be more “resistant” to edema because it is structurally more tightly packed, and thus most PRES lesions are seen in the white matter. There is also a proposed direct cytotoxic effect of various chemotherapeutic and immunomodulatory agents on the vascular endothelium.

PRES is a clinicoradiographic syndrome without specific diagnostic criteria. A high index of suspicion is required to help guide appropriate neuroimaging in a suggestive clinical context. Whereas abnormalities consistent with PRES can be seen on computed tomography (CT) scans, magnetic resonance imaging (MRI), especially FLAIR sequences, are most sensitive for PRES lesions.[56] MRI is also helpful in distinguishing PRES from ischemia and guiding appropriate therapy. The treatment

for PRES is mostly supportive with reduction of hypertension, treatment of seizures, and withdrawal or reducing the dose of the offending agent. It is important to distinguish PRES lesions from ischemia because PRES requires aggressive treatment of hypertension, whereas ischemia is permissive of mild to moderate hypertension. The seizures associated with PRES usually respond well to benzodiazepines, but most case series report using multiple doses and sometimes requiring loading doses of another anti-epileptic medication (eg, phenytoin, phenobarbital) in order to break the seizure.[57,58] Most patients require admission to a pediatric intensive care unit for continued monitoring and optimization of support for vital functions. Rarely, seizures associated with PRES require more aggressive antiepileptic medication in the context of status epilepticus.

Chimeric Antigen Receptor T-Cell–Mediated Toxicity

Clinical trials using T-cell–engaging immunotherapies have shown promise to improve the survival of relapsed leukemia and lymphoma.[59] For pediatrics, chimeric antigen receptor modified T cells (CAR T cells) with specificity against CD19 have especially improved survival in relapsed pre–B-cell acute lymphocytic leukemia (ALL).[60] This unique therapy, however, has unique toxicities. Patients treated with CAR T cells experience a sudden increase in multiple cytokines as the T cells engage the immune system and eliminate leukemic cells. This cytokine release syndrome (CRS), or cytokine storm, is defined as a disorder characterized by fever, nausea, headache, tachycardia, hypotension, rash, and shortness of breath caused by the release of cytokines from cells.[61] CRS is part of the efficacy of the CAR T-cell treatment; however, it can become severe, affecting nearly every organ system including fluid refractory hypotension, tachycardia, cardiomyopathy, acute respiratory failure, neurologic toxicity, and disseminated intravascular coagulation (Fig. 94.3).[59]

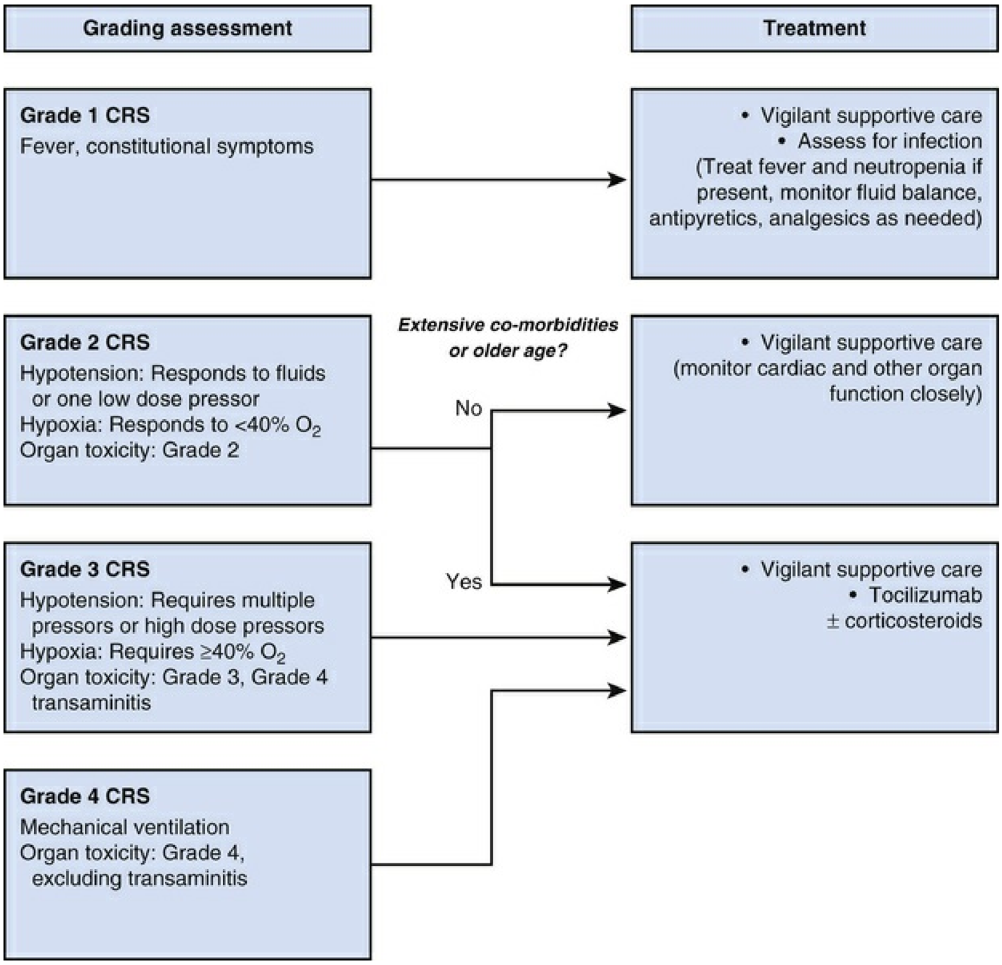

FIG. 94.3 Treatment algorithm for management of cytokine release syndrome. (From Lee DW, Gardner R, Porter DL, et al. Current concepts in the diagnosis and management of cytokine release syndrome. Blood 2014;124:188-194; with permission.)

The timing of symptom onset and CRS severity is likely dependent on tumor burden, baseline cytokine levels, and the underlying genetic predisposition of each patient. The onset of CRS usually happens days to as late as 2 to 3 weeks after the initial infusion and coincides with the maximal in vivo T-cell expansion.[59] The manifestation of CRS in pediatric patients can mimic the clinical presentation of HLH/macrophage activation syndrome (MAS) with highly elevated serum ferritin, D-dimer, aminotransferases, lactate dehydrogenase, triglycerides, hypofibrinogenemia, and hepatosplenomegaly. CRS occurs in about two-thirds of patients treated with CAR T cells.[62] When the syndrome becomes severe or life threatening, inhibition of the inflammatory cascade outweighs further expansion of CAR T cells. Cytokine levels drawn during CAR T-cell therapy indicate IL-6 as a central mediator of toxicity in CRS and have been shown to be a possible target for down regulating the inflammatory cascade.

Tocilizumab is a humanized immunoglobulin antihuman IL-6R mAb approved for treatment of rheumatoid arthritis,[63] juvenile idiopathic arthritis,[64] and polyarticular juvenile rheumatoid arthritis. Clinical experience at several institutions conducting CAR T-cell trials has indicated that tocilizumab is an effective treatment for severe or life-threatening CRS.[65,66] Initial dosing is 8 mg/kg, which is administered over 1 hour. This dose can be repeated in 24 to 48 hours if clinical improvement does not occur.

Clinical response is usually seen within a few hours, with resolution of hypotension and fever allowing for weaning of supportive measures and pressors. If clinical response is not achieved 24 to 48 hours after the administration of tocilizumab, another immunosuppressive agent, such as corticosteroids, should be considered. Corticosteroids are usually avoided because of their probable adverse effect on the antitumor activity of the CAR T cells, although this remains debatable. Dosing and choice of corticosteroid can vary among patients, but an initial dose of methylprednisolone of 2 mg/kg/day can be considered and then weaned over several days, with a preference of dexamethasone in patients experiencing neurotoxicity. As more children are treated with highly active T-cell–engaging therapies, we will continue to gain clinical experience with managing the toxicities of this novel treatment. The continued challenge will be to control the toxicity without interfering with the efficacy.

CHAPTER 95

Critical Illness Involving Children Undergoing Hematopoietic Cell Transplantation

Jennifer McArthur, Christine Duncan, Prakad Rajapreyar, Julie-An Talano, Robert T. Tamburro Jr.

PEARLS

- Patients undergoing allogeneic hematopoietic cell transplant (HCT) experience prolonged immune dysregulation and are at risk for both opportunist infection and graft-versus-host disease (GVHD).
- HCT patients experiencing respiratory symptoms including a new oxygen requirement deserve prompt evaluation by the critical care team as they are at risk for rapid development of respiratory failure.
- Outcomes for HCT patients requiring intensive care unit care have improved since the 1990s.
- Patients who develop GVHD are at high risk for developing other transplant-related toxicities.

Overview

Hematopoietic progenitor cell transplantation has evolved as the treatment for a variety of congenital and acquired malignant and nonmalignant disorders. Over the years the name of this procedure has changed in an attempt to be more accurate. Throughout the literature, it has been referred to as bone marrow transplant (BMT), hematopoietic progenitor cell transplant (HPCT), hematopoietic stem cell transplant (HSCT), and, more recently, hematopoietic cell transplant (HCT).

The first successful pediatric bone marrow transplant occurred in a child with combined immunodeficiency. Reported in 1968, the patient received marrow from a human leukocyte antigen (HLA)-matched sibling.[1] Presently, in adults and children,

the majority of allogeneic transplants are performed for the treatment of malignant disorders such as leukemias and lymphomas, although the field continues to expand to include nonmalignant disorders such as autoimmune disorders, metabolic diseases, immune deficiencies, and hemoglobinopathies. Since its inception, the field of pediatric HCT has demonstrated vast improvements in morbidity and mortality related to transplantation; however, there are still many hurdles to overcome. The major contributors to morbidity and mortality of allogeneic transplantation continue to be relapse of disease, transplant-related toxicity, infection, and graft-versus-host disease (GVHD).

Sources of Hematopoietic Progenitor Cells and Identification of Donors

HCT involves transplanting hematopoietic progenitor cells from a donor source into a recipient. These stem cells are capable of self-renewal and terminal differentiation that ultimately give rise to myeloid cells, lymphocytes, erythrocytes, and platelets (Fig. 95.1). The donor source of these stem cells can be from the patients/recipients themselves (autologous) or from another individual (allogeneic). The source of the donor (autologous versus allogeneic) depends on the indication for which the transplant is being performed. Traditionally, HCT has been performed using stem cells obtained from bone marrow. However, stem cells can be mobilized into the peripheral blood and harvested for transplant. These peripheral blood stem cells (PBSCs) allow for faster hematopoietic recovery and possibly less tumor contamination than bone marrow when used in autologous transplantation. However, there may be more side effects in the allogeneic setting, particularly increased incidence of GVHD.[2]

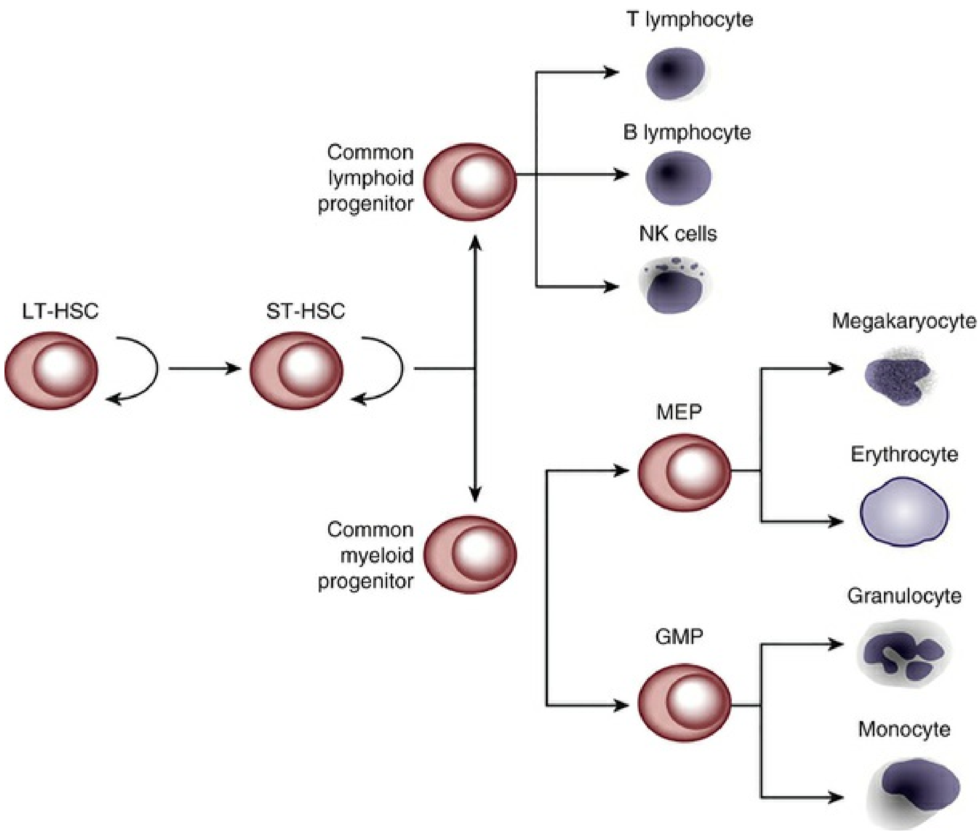

FIG. 95.1 As hematopoietic stem cells divide, they give rise to common lymphoid and common myeloid precursor cells that eventually generate all mature blood lineages of the body. *GMP*, granulocyte-monocyte precursors; *LT-HSC*, long-term hematopoietic stem cells; *MEP*, megakaryocyte-erythrocyte precursors; *NK*, natural killer; *ST-HSC*, short-term hematopoietic stem cells. (Modified from Leung AYH, Verfaillie CM. Stem cell model of hematopoiesis. In: Hematology: Basic Principles and Practice. 4th ed. Philadelphia, 2001, Elsevier.)

Umbilical cord blood has also been shown to contain large numbers of stem cells capable of reconstituting hematopoiesis. The first HCT using cord blood was performed in 1988 for a child with Fanconi anemia.[3] Since then, unrelated cord blood stem cells have been used and numerous public cord blood banks have been established worldwide. These cord blood banks are now regulated by the National Marrow Donor Program.

When no matched unrelated donor or cord blood can be found in a timely fashion, haploidentical transplantation can be performed using a parent or a sibling as donor. Histoincompatibility barriers of a mismatched transplantation are overcome by using megadoses of stem cells. However, for this to be successful, a majority of the T cells have to be removed from the graft to prevent severe GVHD. Unfortunately, this increases the risk for severe infection and relapse of the patient's original disease.[4,5] Centers are utilizing a T-cell replete haploidentical transplantation approach, which incorporates high-dose, posttransplantation cyclophosphamide to promote graft-host tolerance after allogeneic hematopoietic stem cell transplantation.[6]

HLAs are expressed on the surface of various cells, in particular white blood cells (WBCs). These antigens are also known as the major histocompatibility complex with relevant genes on the short arm of chromosome 6.[7] This genetic region has been divided into chromosomal regions, called classes. Classes I and II are important in

transplantation. Class I is made up of HLA-A, HLA-B, and HLA-C, and class II is made up of HLA-DR, HLA-DP, and HLA-DQ, as well as variations on these genes. Traditionally, the loci critical for matching for a bone marrow donor are HLA-A, HLA-B, and HLA-DR. HLA-C and HLA-DQ have gained importance and are now considered in determining the best available donor.[7,8]

Ideally a matched sibling donor is the best donor for a patient. However, only 25% of patients with siblings are fortunate to have a matched sibling donor. If there is no sibling donor, an alternative donor is identified using the National Marrow Donor Program (NMDP), which has approximately 12.5 million potential donors and nearly 150,209,000 cord blood units available for patients who need an HCT.[9] As the degree of mismatch between patient and donor increases, so do the risks of complications from transplant, especially GVHD and graft failure.

Indications and Outcomes

HCT has been used for a variety of diseases. Autologous transplantation has traditionally been used to treat nonhematologic malignant diseases by escalating the doses of chemotherapy to myeloablative doses in hopes of eradicating the cancer. Successive (two or three) autologous transplants have been performed with nonmyeloablative doses of chemotherapy, particularly in brain tumors. The rationale of giving hematopoietic stem cells after the chemotherapy has been completed is to minimize the period of neutropenia, which will hopefully reduce the number of infections and life-threatening complications.[2]

Allogeneic HCT is performed for hematologic cancers. In children these are most commonly acute lymphoblastic leukemia (ALL) and acute myelogenous leukemia (AML). It is also used to treat hematologic diseases including sickle cell anemia, thalassemias, and severe aplastic anemia. A variety of immune deficiencies and metabolic disorders are cured by allogeneic transplant, including severe combined immune deficiency and hemophagocytic lymphohistiocytosis (Table 95.1).[2]

TABLE 95.1

Indications for Pediatric Hematopoietic Progenitor Cell Transplantation

Autologous Transplantation
Malignant Disorders
High-risk neuroblastoma
Relapsed non-Hodgkin lymphoma
Relapsed Hodgkin disease
Medulloblastoma
Germ cell tumors
Brain tumors
Relapsed Ewing sarcoma
Nonmalignant Disorders
Autoimmune disorders
Allogeneic Transplantation
Malignant Disorders
Acute myelogenous leukemia

Acute lymphoblastic leukemia
Chronic myeloid leukemia
Myelodysplastic syndromes
Juvenile myelomonocytic leukemia
Nonmalignant Disorders
Aplastic anemia
Fanconi anemia
Severe combined immunodeficiency
Thalassemia major
Diamond-Blackfan anemia
Sickle cell anemia
Wiskott-Aldrich syndrome
Osteopetrosis
Inborn errors of metabolism
Hemophagocytic lymphohistiocytosis
Shwachman-Diamond syndrome
Congenital immune deficiencies

Survival from HCT has improved. In autologous transplantation the incidence of treatment-related mortality is less than 10%. However, the majority of treatment failures are due to recurrent disease. Specifically the event-free survival rate for autologous HCT for high-risk neuroblastoma ranges from 33% to 66%.[10-14] For recurrent or refractory non-Hodgkin lymphoma the event-free survival in autologous HCT ranges from 27% to 59%.[15] In relapsed or refractory Hodgkin disease the event-free survival ranges from 20% to 62%.[15]

Among children with ALL, allogeneic transplantation is generally reserved for patients with high-risk disease, patients who fail to achieve remission, or patients who relapse after chemotherapy. Among the 2096 patients younger than 20 receiving an HLA-matched sibling transplant for ALL between 2002 to 2012, the 3-year survival rates range from 26% to 67% depending on their disease status going into transplant. The corresponding survival rates among the 3291 recipients of an unrelated donor transplant range from 31% to 66%.[16] For pediatric patients with AML transplanted with matched siblings donors between 2002 and 2012, the 3-year survival rates following transplant range from 30% to 66%.[16] For unrelated donor transplants the 5-year overall survival rates range from 20% to 50%.[16]

Allogeneic HCT is the treatment of choice for young patients with severe aplastic anemia and an available HLA-matched sibling donor. These patients have excellent outcomes with survival rates ranging from 73% for unrelated donor transplants to 88% for matched sibling transplants.[16] Transplant outcomes for other nonmalignant diseases are also improved, with Fanconi anemia patients having a 5-year overall survival of 60% to 75%,[17-19] Wiskott-Aldrich disease at 90%, and severe combined immune deficiency at 71%.[20] For inherited metabolic disorders, the overall survival of pediatric patients with adrenoleukodystrophy/metachromatic leukodystrophy is approximately 60% and for Hurler syndrome it is approximately 70% when using unrelated donor transplants facilitated by the NMDP from 2001 to 2010.[21-23]

Transplant Procedure

Conditioning Regimen

Patients undergoing HCT are subjected to a treatment regimen referred to as a conditioning regimen or preparative regimen prior to infusion of the hematopoietic progenitor cells. The purpose of this preparative regimen is multifold. In cases of malignant disorders, it eradicates disease. In addition, the preparative regimen must be immunosuppressive in allogeneic transplantation to allow the donor cells infused to establish themselves in the marrow cavity and overcome host rejection. The precise conditioning regimens can include chemotherapy alone or in combination with radiation. Numerous regimens have been explored and are dependent on the disease for which the transplant is required and the research interests of the institution performing the transplant.

Stem Cell Harvesting/Collection/Cryopreservation

Stem cells can be collected or harvested from either bone marrow or peripheral blood. For patients or donors undergoing bone marrow harvest, general anesthesia or regional anesthesia is given. Bone marrow is generally aspirated using special bone marrow harvest needles percutaneously from the posterior iliac crests using numerous passes. The amount of marrow taken is based on the size of the recipient. If there is a significant size discrepancy between the donor and the recipient (recipient larger than the donor), the donor may lose a significant amount of blood. Donors can be placed on iron therapy after harvest, or they can electively store autologous blood ahead of time. A newer technique allows for the collected marrow to be processed with removal of red blood cells (RBCs) (particularly necessary in cases of major ABO incompatibility between donor and recipient), and these RBCs can be transfused to the donor postoperatively.

Peripheral blood stem cells can be mobilized in patients recovering from chemotherapy (autologous) or by giving allogeneic donors cytokines such as G-CSF. Their stem cells then can be collected using an apheresis machine in an outpatient setting. Collection of sufficient cells for transplantation may require several apheresis procedures. Stem cells for allogeneic transplantation usually are collected on the day they are anticipated to be reinfused into the patient. Autologous collection of stem cells requires cryopreservation of the cells until the day of reinfusion. Dimethyl sulfoxide (DMSO) is added to the collection product to ensure cell viability, and the cells are frozen in liquid nitrogen until needed.

Stem cells can be collected from umbilical cord blood. After delivery of the infant, sterile umbilical venous access is obtained and the blood is collected into anticoagulated tubes. This can be done either before or after delivery of the placenta. A sample of this cord blood is used for HLA typing and infectious disease testing; the remainder is cryopreserved.

Reinfusion

The day of stem cell reinfusion is referred to as day 0 for the transplant period. Cryopreserved stem cells are thawed in a water bath under sterile conditions and may be washed to remove the DMSO cryopreservant. Stem cells then are infused

into the patient though the indwelling central venous catheter. These cells are capable of migrating into the bone marrow on their own. Blood transfusion–like complications can occur with reinfusion of stem cells, and patients are generally placed on cardiac monitors with emergency medications available at the bedside during the infusion. The infusion procedure is generally short, lasting anywhere from approximately 10 minutes to 4 hours, depending on the volume of cells infusing.

Recovery Period

After the reinfusion of stem cells, patients wait for count recovery to occur and receive treatment for any toxicities. Allogeneic transplant patients receive immunosuppressive medicines to prevent GVHD. Most patients are hospitalized for the entire transplant procedure, starting with the conditioning regimen. However, there is a trend toward outpatient HCT, particularly in the autologous setting. A typical hospitalization for HCT is 4 to 6 weeks, but it may be prolonged if umbilical cord blood is used or shortened for autologous transplants.

Complications

Patients undergoing HCT are at high risk for complications that may require a stay in the pediatric intensive care unit (PICU). In one series, 19% of pediatric HCT patients required a PICU admission.[24] In other published series, 6% to 25% of pediatric HCT patients required mechanical ventilation.[25,26] Because of the high use of critical care services by HCT patients, it is beneficial for the pediatric intensivist to be familiar with their complications.

The reasons for these patients being at high risk for critical illness are multifactorial. Many of these patients are undergoing HCT for an underlying disease that places them at risk for critical illness such as malignancies, severe immunodeficiencies, and metabolic disorders. To make room for the new hematopoietic progenitor cells, patients are given conditioning regimens with high doses of toxic chemotherapy or radiation. This makes them severely immunocompromised, placing them at high risk for opportunistic infections. The conditioning agents themselves cause significant oxidative stress and may be the common denominator behind many of these complications.[27]

Although mortality rates for HCT patients requiring ICU care are quite high in comparison to the general ICU population, they appear to be improving. Data from the 1980s showed mortality rates for mechanically ventilated pediatric HCT patients to be near 90%.[26,28] However, more recent data indicate the mortality rates to be closer to 60%.[29-31] In a single institution report, HCT patients requiring vasoactive-inotropic support due to sepsis had PICU mortality rates of 30%. In the subgroup of septic patients requiring both vasoactive-inotropic support and mechanical ventilation, mortality rates were 74%.[32] Some of the improvements seen in outcomes over the years may be due to differing characteristics of the patients, as few studies reported severity of illness scores.[28] In any case, no series reporting on mortality of pediatric HCT patients was able to predict with 100% certainty that a given patient would not survive. Therefore the critical care and transplant teams must work together and use their best judgment when making recommendations to families

regarding the appropriateness and duration of critical care services for this complex patient population.

Cardiac Complications

Cardiac complications following HCT can occur during the immediate transplant period or be late sequelae in survivors. The heart may be injured during the transplant process from a variety of pathophysiologic etiologies.[33,34] First, previous cardiotoxic treatments and therapies such as anthracyclines and iron overload from frequent red cell transfusions may predispose the heart to subsequent injury during transplantation. In addition, cardiotoxic therapies such as cyclophosphamide and irradiation used as part of the preparative regimen may further injure the recipient heart.[35-37] Moreover, hyperhydration therapies, blood product transfusions, and impaired renal function may place further stress on the heart. Sepsis, which commonly affects the HCT patient, has also been found to decrease cardiac contractility.[38] More specific to the HCT patient, there are rare reports of acute GVHD affecting the heart and cardiovascular system.[39] Further, transplant-associated thrombotic microangiopathy has been associated with cardiovascular complications such as pericardial effusions and pulmonary arterial hypertension.[40,41] Additionally, in a small series of children treated for a primary immunodeficiency with HCT (n = 10), cardiac chamber hypertrophy was reported to occur in those transplanted at less than a year of age and who received high-dose corticosteroids for acute GVHD.[42] Finally, there is evidence to suggest that genetic susceptibility may also play a role in HCT-related heart failure. For example, using a nested case-control study design, it was noted that polymorphisms in the NAD(P)H oxidase subunit RAC2 as well as carbonyl reductase CBR1 were associated with a significant increase in the risk of acute heart failure among HCT recipients. These findings suggest that acute heart failure occurs as a result of oxidative stress or metabolic derangements induced by cardiotoxic alcohol metabolites of anthracyclines and that variants of RAC2 and CBR1 modulate this risk.[43]

Although the heart and cardiovascular system are at risk from these various processes, cardiac complications are relatively rare in the early posttransplant period after HCT. In an analysis of 2821 adult and pediatric patients, only 26 (0.9%) experienced a major or fatal cardiac complication in the first 100 days after transplant.[44] Seven of the 26 cardiac complications occurred in children. Given the median age of 22 years in that trial, an incidence of approximately 0.5% may be inferred for pediatric HCT recipients. Among the 26 patients with significant cardiac complications, 11 had evidence of heart failure, 5 had pericardial tamponade, and 10 had dysrhythmias.[44] All 11 patients with heart failure died compared with only one each with tamponade or a dysrhythmia. All cases of heart failure occurred between day −6 and day +35. Four of the seven pediatric patients had heart failure. In another report, the Associazione Italiana Ematologia Oncologia Pediatrica-BMT Group described its transplant-related toxicities in 636 pediatric patients transplanted for acute leukemia.[45] In the group's experience, the incidence of moderate or severe cardiac toxicity in the first 90 days posttransplant varied by the type of transplant with autologous recipients experiencing an incidence of 1.9% (4 in 216, two deaths) and allogenic recipients of a compatible related donor experiencing a comparable incidence of 2.4% (7 in 294, four deaths). However, recipients of an allogeneic

alternative donor experienced a 6.4% rate of these cardiac complications (8 in 126) with all eight experiencing an early death. In that study, the presence of moderate or severe cardiac toxicity increased the relative risk of an early posttransplant death more than ninefold (relative risk, 9.1; 95% confidence interval, 2.8 to 29.6) and more so than toxicity to any other organ system. The manifestations of the cardiac disease are varied and include myocardial ischemia, dysrhythmias, pericardial effusion, pericarditis, and progressive congestive heart failure. One particular cardiovascular complication that merits special attention in the pediatric HCT patient is the occurrence of pulmonary hypertension.

Pulmonary arterial hypertension in the setting of pediatric HCT is reported with increased frequency. In one report, a routine day +7 echocardiogram detected elevated right ventricular pressures in 13% of the patients.[46] In that report, and others, the pulmonary arterial hypertension is found to be associated with transplant-associated thrombotic microangiopathy.[41,46] Additionally, pulmonary arterial hypertension is reported to occur in the setting of patients undergoing transplant for malignant infantile osteopetrosis.[47] Pulmonary venoocclusive disease may also account for episodes of pulmonary arterial hypertension.[48] The incidence of pulmonary venoocclusive disease in HSCT patients is speculative given the limited available data.[48] Pulmonary hypertension is reported to be the proximate cause of death in pediatric patients undergoing HCT for hemophagocytic lymphohistiocytosis and idiopathic myelofibrosis.[49,50] Independent of the cause, pulmonary arterial hypertension should always be suspected in the pediatric HCT patient with unexplained cardiopulmonary dysfunction as emergent therapy may be lifesaving.

An accepted scoring system based on previously published grading of cardiac toxicities following stem cell transplantation consists of the following[44]:

Grade I: (1) Cardiomegaly on chest radiograph without symptoms, (2) mild electrocardiogram changes not requiring treatment, (3) asymptomatic pericardial effusion

Grade II: (1) Moderate electrocardiogram changes requiring and responding to medical intervention, (2) congestive heart failure requiring and responding to afterload reduction, diuretics, and digitalis, (3) pericarditis

Grade III: (1) Severe electrocardiogram abnormalities with no or only partial response to medical intervention, (2) congestive heart failure requiring inotropic support, (3) cardiogenic shock, (4) a decrease in QRS voltage by more than 50%, (5) pericardial tamponade

Grade IV: Fatal toxicity

Late cardiovascular toxicity occurring a year or more after HCT has also been reported.[51-53] Late cardiovascular complications following HCT included heart failure, dysrhythmias, hypertension, and cerebrovascular accidents. Several pathologic mechanisms of late congestive heart failure have been offered including the same mechanisms causing acute heart failure such as previous cardiotoxic agents (anthracyclines, alkylating agents, thoracic irradiation) in conjunction with cyclophosphamide and total body irradiation during conditioning regimens. A

report evaluating long-term health outcomes in three groups revealed that survivors of childhood HCT had a 13-fold increased risk of severe cardiovascular complications when compared to healthy sibling controls but had an equivalent risk to that observed in conventionally treated childhood cancer survivors.[43,54] In one report of 155 long-term pediatric survivors of HCT with a median length of follow-up of 9 years, 14 were found to have hypertension, 4 were found to have abnormal asymptomatic electrocardiograms, and 4 were found to have abnormal asymptomatic echocardiograms.[53] All patients in that report had a left ventricular shortening fraction greater than 30%. In another report of 112 children who received an allogeneic HCT and survived at least 1 year, 11 had abnormal echocardiographic findings, 8 had hypertension, and 2 had cerebrovascular accidents.[55] The probability of developing a cardiovascular complication at 10 years was 11% ± 3% in that report. Moreover, among patients who developed a cardiac complication, all had received total body irradiation. Other factors such as the presence of chronic GVHD and patient characteristics such as age, size, and gender may play a role in late congestive heart failure. Total body irradiation, both alone and in conjunction with pretransplant anthracycline use, was also associated with a negative impact on cardiac function 5 years after transplant in a cohort of 162 pediatric patients who underwent allogeneic HCT for both malignant and nonmalignant diseases.[56] In that study, 14 (12%) of the 119 patients with pretransplant echocardiograms were found to have abnormal shortening fractions at the time of transplant. The cumulative incidence of shortening fraction abnormalities increased to 26% by the fifth year of follow-up in that report. In another study, assessing cardiac function during cardiopulmonary exercise testing revealed a significantly decreased maximal cardiac index in 33 children who had undergone HCT in longitudinal follow-up.[57] Although no patient experienced a dysrhythmia or had electrocardiographic evidence of ischemia, four patients were found to have a shortening fraction less than 28%. Based on the finding of a decreased maximal cardiac index and a normal peak heart rate, the authors concluded that this provided evidence of long-standing subclinical cardiac dysfunction in this patient population. In a long-term follow-up (median = 12 years) of 204 pediatric allogeneic HCT patients, the most common cardiovascular complications were hypertension (7%) and left ventricular dysfunction (3%).[51]

Despite the relatively low incidence of overt cardiac dysfunction, subclinical cardiac dysfunction appears relatively common in pediatric HCT recipients and may portend a poor outcome. For example, in a case control study of 40 consecutive pediatric HCT patients, HCT patients were found to have similar left ventricular ejection fractions as controls.[58] However, the HCT recipients were found to have significantly decreased rate-corrected velocity of circumferential fiber shortening, mitral inflow E velocity, and mitral septal annular E′ velocity. Using speckle tracking echocardiography, HCT patients were also noted to have decreased left ventricular global circumferential systolic strain, strain rate, circumferential diastolic strain rate, and longitudinal diastolic strain rate. Also, pericardial effusion, which has been reported to occur in approximately 17% of pediatric HCT recipients, is asymptomatic in approximately half of the cases and is rarely the proximal cause of death.[40] Despite that observation, HCT patients with a pericardial effusion have a significantly increased risk of mortality. A pretransplant prolonged corrected QT dispersion may help identify patients at risk for a pericardial effusion.[40,59] In another report, 100 pediatric HCT patients underwent a routine, scheduled echocardiogram at day +7.[46]

At least one abnormality was noted in 30% of the children, most commonly a pericardial effusion or an elevated estimated right ventricular pressure. Survival was decreased in children with any abnormality detected. In addition to echocardiography and electrocardiography, biomarkers may also identify patients at risk for cardiac dysfunction. Elevations in NT-proBNP concentrations at day 14 after stem cell transplant can identify patients at risk of developing cardiac events during the first 6 months after HCT.[60,61]

In summary, cardiac toxicity appears to be an uncommon, although serious, complication following HCT. It may present as an acute finding in the immediate posttransplant period with evidence of progressive heart failure, dysrhythmias, and pericardial effusions with tamponade. Late cardiovascular complications are also being studied. Although clinically evident late cardiac complications are being reported, there appears to be a number of subclinical findings detected by use of more involved testing. The importance of these subclinical findings is likely to be better understood as these children age further.

Pulmonary Complications

The incidence of HCT-related pulmonary complications in children is reported between 12% and 25%.[62,63] The need for mechanical ventilation support is the most frequent reason for admission of HCT patients to the PICU.[24,31] Pulmonary complications can be divided into early and late complications (Table 95.2). Early complications occur within the first 100 days after transplant. The division into early and late complications is not absolute but may help the clinician in developing a differential diagnosis. Early complications include infection, peri-engraftment respiratory distress syndrome (PERDS), pulmonary cytolytic thrombi (PCT), diffuse alveolar hemorrhage (DAH), and idiopathic pneumonia syndrome.[64] Late-onset complications occur beyond 3 months after HPCT and include bronchiolitis obliterans (BO), bronchiolitis obliterans organizing pneumonia (BOOP), and idiopathic pneumonia syndrome (IPS).[65]

TABLE 95.2

Pulmonary Complications of Hematopoietic Progenitor Cell Transplantation

Complications	Characteristics	Treatment
Early-Onset Pulmonary Complications		
Infection	Positive test for infection	Antimicrobials
Diffuse alveolar hemorrhage	Progressive bloody return on BAL	Corticosteroids, FFP, plasmapheresis
Idiopathic pneumonia syndrome	Diffuse noninfectious lung injury	Etanercept
Engraftment syndrome	Periengraftment pulmonary edema	Corticosteroids
Late-Onset Pulmonary Complications		
Bronchiolitis obliterans	Obstructive lung disease	Corticosteroids, macrolides
Bronchiolitis obliterans organizing pneumonitis	Restrictive lung disease	Corticosteroids
Idiopathic pneumonia syndrome	Diffuse noninfectious lung injury	Etanercept
Pulmonary venoocclusive disease	Pulmonary hypertension	Sildenafil, prostacyclin, defibrotide

BAL, bronchoalveolar lavage; *FFP*, fresh frozen plasma.

Early Pulmonary Complications

Periengraftment Respiratory Distress Syndrome

Periengraftment respiratory distress syndrome (PERDS) occurs just as patients begin to show signs of neutrophil recovery. This syndrome is likely caused by pulmonary leukoagglutination and inflammatory cytokines. Patients may develop fever, rash, fluid retention, capillary leak, and pulmonary edema. In severe cases patients can develop multiorgan involvement.[66] Engraftment syndrome may be related to a graft-versus-host response or in some cases a host-versus-graft response. In mild cases no treatment is necessary.[66] In more severe cases, particularly if there is lung involvement, corticosteroids can be beneficial.[66-68] Survival from PERDS is quite good in comparison to other pulmonary complications of HCT, in excess of 90%.[69]

Pulmonary Cytolytic Thrombi

Pulmonary cytolytic thrombi (PCT) is a rare pulmonary complication of HCT. It was first described in a small case series of 13 patients published in 2000.[70] Patients in this series presented with fever at a median of 72 days after HCT (range, 8–343 days). Two of the 13 patients also had a cough at presentation. Chest CT performed on these patients revealed pulmonary nodules. Pathologic exam showed necrosis and basophilic thromboemboli in the nodules. Immunohistochemical staining showed the nodules to contain entrapped leukocytes and disrupted endothelium.

Further publications of PCT describe the pulmonary nodules seen on CT as being bilateral and located primarily in the periphery, subpleural, and basilar areas of the lungs.[71] Further investigation of pathologic samples discovered the leukocytes to be monocytes[72] and described the lung parenchyma adjacent to the nodules to often be infarcted, likely secondary to entrapped debris in surrounding vessels.[71] PCT seems to be responsive to treatment with cyclosporine and corticosteroids. Both radiologic and clinical improvement may be seen within 1 to 2 weeks of beginning treatment.[70,73] Development of PCT in leukemia patients undergoing HCT may be associated with the benefit of decreased risk of relapse.[71]

Diffuse Alveolar Hemorrhage

Alveolar hemorrhage may be infectious or noninfectious in etiology. However, the term *DAH* in an HCT patient generally refers to a noninfectious etiology. The reported incidence ranges from 1% to 21% of HCT patients, with the highest incidence seeming to be in patients with mucopolysaccharide storage diseases.[74,75] It usually occurs in the early posttransplant period and is characterized by widespread alveolar injury, absence of infection, and progressively bloodier return of bronchoalveolar lavage fluid during bronchoscopy.[76] Patients commonly present with respiratory distress and fever and less commonly have hemoptysis.[76] It can occur in both autologous and allogeneic transplants.[76] The exact etiology of DAH is unknown, but like other noninfectious pulmonary complications it is associated with GVHD and engraftment.[77-79] Endothelial injuries from chemotherapy and radiation, inflammation, undiagnosed infections, and immune-mediated damage related to GVHD have all been postulated as the cause.[76,78]

Successful use of high-dose corticosteroids has been reported in case reports of DAH.[76,80] However, no prospective studies have proved the benefit of this therapy.[76,78] Despite this observation, they remain standard of care for DAH. Fresh frozen plasma transfusions and plasmapheresis have been tried but are of uncertain

benefit.[76] Recombinant factor VIIa has been used for refractory bleeding in these patients[81] but has not been shown to have an impact on survival.[82] Aminocaproic acid used in conjunction with corticosteroids has been described in a series of eight patients with DAH refractory to corticosteroids. The overall 100-day mortality for these eight patients was 44%, an improvement over those treated with corticosteroids alone where the 100-day mortality was 83%.[83]

Idiopathic Pneumonia Syndrome

The incidence of IPS in pediatric HCT patients has been reported to be between 2% and 15%.[63,65,84-86] IPS is usually considered an early complication of transplant, but it has also been described as a late complication. The diagnosis is made by meeting the diagnostic criteria set by an expert panel convened by the National Institutes of Health (NIH) in 1993. Patients must show evidence of widespread lung injury as confirmed radiographically by bilateral lung disease, signs and symptoms of pneumonia (cough, dyspnea, or rales), abnormal lung function (increased alveolar to arterial oxygen gradient, pulmonary function testing with restrictive lung disease), and the absence of an infectious etiology.[87]

The term *IPS* is often used interchangeably with idiopathic pneumonitis and interstitial pneumonitis in the literature. However, interstitial pneumonitis is the histopathologic description in some cases of IPS. Other cases of IPS will show histopathologic findings consistent with DAH or BOOP.[87] IPS, interstitial pneumonitis, DAH, BOOP, and BOS are all considered noninfectious pulmonary complications of transplant. As prevention and treatment of infectious pulmonary complications have improved, these noninfectious complications are now the more troublesome.[88]

The literature continues to be confusing regarding the nomenclature of these noninfectious pulmonary complications of transplant. It is important for the critical care physician at the bedside to treat his or her patient appropriately without becoming anguished over the particular name of the disease. Though corticosteroids and etanercept, a tumor necrosis factor-alpha (TNFα) receptor antagonist, may prove to be beneficial in some cases, at the present time there is no definitive treatment for any of the noninfectious pulmonary complications. Therefore providing excellent supportive care in the ICU by paying close attention to fluid balance and utilizing lung protective strategies during mechanical ventilation are likely the most important aspects of care we can provide.

Inflammation plays a significant role in the development of IPS. GVHD is known to be associated with high levels of inflammatory cytokines. GVHD has consistently been shown to be associated with IPS.[65,84,89] Because of this association, there is debate in the literature as to whether IPS actually represents GVHD of the lung.[87] However, the histopathology of IPS often does not resemble that of acute GVHD, which typically involves epithelial cell apoptosis.[85]

In the mouse models of IPS when TNFα knockout mice are used as recipients, the mice develop IPS like wild-type mice. However, when TNFα knockout mice are used as donors for wild-type recipients, the severity of IPS is significantly less. In this model, TNFα is derived from donor T cells.[90] This animal model fits the clinical observation that patients who receive T-cell–depleted grafts have a lower incidence of pulmonary complications.[91,92]

Some cases of IPS may be caused by an unidentified infection. A retrospective

study of stored BAL samples from HCT patients with pulmonary complications detected human metapneumovirus in 5 (3%) of 163 patients. Three of the 5 patients were diagnosed with IPS. On review of these patients' medical records, they initially presented in the first 40 days after transplant with typical upper respiratory symptoms: fever, cough, nasal congestion, and sore throat. Four of the five patients died of rapidly progressive acute respiratory failure. Three of the 5 had DAH.[93]

Because of the role of inflammation in IPS, corticosteroids have been used as therapy but have not been shown to be universally efficacious.[65,94] Therefore because TNFα has been shown to be an important mediator in mouse models of IPS, the soluble TNFα-binding protein, etanercept, has been used. Etanercept showed promise in an early phase I/II trial when given with systemic corticosteroids to patients with IPS. Ten of 15 patients treated on the protocol were able to be weaned from supplemental oxygen.[95] A retrospective study comparing etanercept and corticosteroids versus corticosteroids alone showed improved survival in the patients receiving etanercept.[96] These promising results lead to a phase II trial of etanercept in pediatric IPS patients. These results were also encouraging with a response rate of 71%, 28-day survival of 89%, and 1-year survival of 63%.[97] These results were in contrast, however, to the parallel adult study where the 1-year survival was <25%.[98] There were significant transplant-related differences between the adult and pediatric patients that could explain the differences in outcomes. The adult patients were also much less compliant with the etanercept dosing in comparison to the pediatric patients.[85]

Continuous venovenous hemofiltration has also been used in patients with acute lung injury after chemotherapy and HCT (see also Chapter 78). In a series of 10 patients, 7 had a noninfectious lung injury. Four of these 7 were HCT patients. All patients were mechanically ventilated and met criteria for ARDS. Three of the four HCT patients with noninfectious lung injury survived to extubation.[99]

Lung transplantation has been reported in children who have developed chronic respiratory failure as a complication of HCT in multiple case series in the literature.[100-104] Of the patients reported, survival appears to be comparable to lung transplantation in the general populations. Therefore this may be an appropriate option in select patients.

Calfactant (calf lung–derived surfactant) may play a role in the treatment of acute lung injury after HCT. A post-hoc analysis of a multicenter trial of calfactant in mechanically ventilated pediatric patients with acute lung injury showed possible benefit in the subgroup of immunocompromised patients. Twenty-seven of the 52 immunocompromised patients analyzed had undergone HCT. In this subgroup analysis, patients who received calfactant had a 50% mortality rate, whereas those receiving placebo had a 60% mortality rate.[105] A trial of calfactant in pediatric patients with acute lung injury with leukemia, lymphoma, or history of HCT is currently under way.

Extracorporeal membrane oxygenation (ECMO) has infrequently been used as a heroic measure for HCT patients with severe lung injury. In reviews of the Extracorporeal Life Support Organization (ELSO) database published in 2008, there were no ECMO survivors with a history of recent HCT.[106] However, there was one case report in the literature of an 8-month-old girl with severe combined immunodeficiencies who was transplanted while symptomatic with bronchiolitis. ECMO was used successfully as a bridge to engraftment.[107] A review of the ELSO

database reported 3 survivors to hospital discharge of the 29 pediatric HCT patients who received ECMO support after HCT.[108] The authors of this report concluded that although outcomes of ECMO in HCT patients are poor, it should be considered in select patients who received HCT for a nonmalignant condition or a malignancy with a low risk of relapse.

Late Pulmonary Complications

Bronchiolitis Obliterans Syndrome/Bronchiolitis Obliterans Organizing Pneumonia

Bronchiolitis obliterans syndrome (BOS) and BOOP are late-onset noninfectious pulmonary complications of HCT. Both of these complications are associated with chronic graft-versus-host disease and are much more commonly seen after allogeneic transplant as opposed to autologous transplant.[92,109,110] The NIH developed consensus criteria for BOS in 2005, with a proposed amendment in 2009, to facilitate communication in the literature. The amended criteria include (1) absence of an infectious etiology, (2) evidence of chronic GVHD at another site, (3) forced expiratory volume <75% predicted or a decline of >10% from previous, and (4) forced expiratory volume in 1 sec/forced expiratory vital capacity <0.7 or residual volume/total lung capacity >120% and computerized tomography findings of air trapping or bronchiectasis.[110]

The pathophysiology of BOS likely involves donor T cells causing an immune-mediated injury to lung epithelial cells. This injury then causes the release of inflammatory mediators leading to fibroblast migration, smooth muscle cell proliferation, and eventual deposition of collagen and fibrin in the airway lumens.[110] Risk factors for the development of BOS include busulfan conditioning,[111] allogeneic transplant,[110] recurrent pulmonary infections,[112] and chronic graft-versus-host disease.[113-115]

Patients with BOS typically present 6 to 12 months after HCT, are afebrile, and have nonspecific symptoms such as a nonproductive cough and exertional dyspnea.[110] They may have a history of recurrent respiratory infections and graft-versus-host disease. Radiographic findings, pulmonary function testing, and pathology findings from lung biopsy are used to make the diagnosis.[110] Patients with BOS have an obstructive pattern on pulmonary function testing. On high-resolution chest computed tomography (CT) both high and low attenuation areas are seen, as are bronchial dilatation, bronchial thickening, vascular attenuation, and expiratory air trapping. Biopsy specimens show submucosal bronchiolar fibrosis and luminal narrowing and obliteration.[109]

BOOP is also known as cryptogenic organizing pneumonia. Patients with BOOP may present 2 to 6 months after HCT, which is earlier than BOS.[110] They also tend to present more acutely than patients with BOS, presenting with fever, cough, dyspnea, and rales.[110] Patients with BOOP have patchy air space disease on chest radiograph. High-resolution chest CT shows ground-glass opacifications, areas of consolidation, and pulmonary nodules.[109] As opposed to patients with BOS, pulmonary function testing in BOOP shows a restrictive lung disease pattern. Biopsy specimens of BOOP show granulation tissue in the distal airways, alveolar ducts, and peribronchial alveolar space.[88,116] Similar to BOS, the pathophysiology seems to involve T cells and inflammatory cytokines leading to alveolar epithelial cell injury.[110]

For both BOS and BOOP it is recommended that patients undergo bronchial alveolar lavage to rule out infection. BOS may be diagnosed on clinical grounds to avoid open lung biopsy and its associated risks. The diagnosis of BOOP generally requires biopsy. However, a transbronchial specimen is often sufficient.[109]

The number of patients with BOS or BOOP reported in the literature is small. Therefore it is difficult to make firm recommendations regarding treatment or prognosis. BOOP seems to have a better prognosis than BOS and may be reversible, whereas the goal of therapy in BOS is stabilization of disease. It is thought that making the diagnosis early in order to begin therapy when the disease is less severe may be of benefit. Therefore serial pulmonary function tests are currently recommended in HCT patients at risk for pulmonary complications.[113] BOS and BOOP may respond better to corticosteroids than other noninfectious pulmonary complications of HCT.[65,88] First-line therapy for these complications remains a systemic corticosteroids burst with a prolonged taper over several months. There may be some role for combination therapy with inhaled fluticasone, azithromycin, and montelukast to enable a decrease in the dose of systemic corticosteroids.[110] Macrolide therapy may benefit patients with BOS after HCT but requires further study.[117] Other therapies such as inhaled cyclosporine, etanercept, infliximab, and extracorporeal photochemotherapy have been described in case reports for BOS and require further study.[109]

Pulmonary Veno-occlusive Disease

Case reports of pulmonary veno-occlusive disease (PVOD) in HCT patients have been infrequently described. Patients have presented both early and late after HCT with increasing dyspnea and signs of right heart failure. Cardiomegaly and pulmonary edema are seen on chest x-ray. Pulmonary hypertension is seen on echocardiogram. In patients who have undergone cardiac catheterization, high right atrial pressure, right ventricular pressure, and pulmonary artery pressures are seen, whereas the pulmonary artery wedge pressure is frequently normal. Pathologic specimens show fibrosis of the venules and small pulmonary veins, whereas the larger pulmonary veins are typically normal. Because the resistance to flow in the pulmonary veins is typically normal in PVOD, the pulmonary artery wedge pressure appears normal despite having increased resistance through pulmonary venules and small pulmonary veins. Pulmonary arterial intimal fibrosis and hypertrophy may also be seen.[48,118] Pulmonary function testing (PFT) is normal for forced expiratory lung volume, functional vital capacity, and total lung capacity, but carbon monoxide diffusing capacity is typically <50%.[119]

Lung biopsy has historically been the gold standard for diagnosis for PVOD; however, this procedure carries a high risk of complication. Mineo and coworkers reported that the presence of two of three characteristic CT findings (ground glass appearance, septal thickening, and mediastinal lymphadenopathy) was able to diagnose PVOD with 95.5% sensitivity and 89% specificity.[119] Therefore clinical suspicion, PFT, and CT findings may be sufficient to make the diagnosis. There may be a genetic predisposition to PVOD as abnormalities in the bone morphogenetic receptor type II are reported in both PVOD and pulmonary hypertension patients.[110] Corticosteroids, other immunosuppressive agents, and anticoagulation have been used without notable benefit. Sildenafil with prostacyclin has been reported to be of some benefit in treating the pulmonary hypertension. However, these should be

used with caution as they may make some patients worse by causing an increase in pulmonary edema.[110] Theoretically, defibrotide may be beneficial given its efficacy in hepatic venoocclusive disease (VOD), but there are no available reports of its use in patients with pulmonary VOD.[48,118]

Dilemmas in the Diagnosis of Pulmonary Complications

As HCT patients with pulmonary complications are frequently tenuous, placing these patients at risk for complications from diagnostic procedures is a difficult decision. Although it is difficult to treat these critically ill patients without a firm diagnosis, it is also unpalatable to worsen the patient's condition while performing a diagnostic procedure that does not result in a diagnosis. Therefore the debate continues in the literature and at the bedside regarding the risk/benefit ratio of invasive diagnostic procedures such as bronchial alveolar lavage (BAL) and lung biopsy.

St. Jude Children's Hospital published data regarding the diagnostic yield of BAL at the institution.[120] BAL identified the cause of respiratory symptoms in 53 (67.9%) of 78 allogeneic patients and 7 (63%) of 11 autologous patients. The most common finding diagnosed on BAL was bacterial infection (52%). The patients tolerated the procedure well with complications noted in less than 20%. In this series, transbronchial biopsy added information in only 2 of 7 patients. The researchers also noted that 14 of 16 patients who underwent open-lung biopsy already had a positive BAL. The authors concluded that BAL had a beneficial risk/benefit profile and was useful in identifying patients who had an infectious etiology to their lung injury. However, biopsy did not add significantly more information but carried an unacceptable morbidity rate of 47%.

A meta-analysis including 72 studies of BAL and 31 studies of lung biopsy in both pediatric and adult patients found that BAL was superior to lung biopsy for diagnosing an infectious etiology of lung injury, whereas lung biopsy was superior for diagnosing noninfectious lung injury.[121] Either technique led to a diagnosis in over 50% of procedures. Complications were reported at 8% for BAL and 15% for biopsy. Complications of lung biopsy were higher in children than adults ($p = .003$). It was also noted that the addition of BAL galactomannan significantly improved the ability to detect invasive fungal infections. The authors concluded that a reasonable approach was to begin the diagnostic workup with BAL, particularly if infection was suspected, and proceed to biopsy if a noninfectious etiology became more suspect.

Hepatic Complications

Hepatic complications of hematopoietic cell transplantation have been a common cause of morbidity and mortality since the inception of the procedure.[122-126] The complications include hepatic infections (viral, fungal, and bacterial), cholestasis, drug toxicity, sinusoidal obstruction syndrome (SOS) (which is more commonly known as veno-occlusive disease [VOD]), and GVHD. HCT patients may also have an underlying liver disease going into HCT such as tumor infiltration, chronic hepatitis, iron overload, or extramedullary hematopoiesis.[122,126-128]

Viral hepatitis can be caused by any viral pathogen, including hepatitis C, cytomegalovirus (CMV), Epstein-Barr virus (EBV), hepatitis B, adenovirus, herpes

simplex, and varicella zoster. The diagnosis of these pathogens is based on clinical manifestations, with identification of the virus determined (1) histologically, (2) by culture of blood or tissue, or (3) by the presence of viral antigen or nucleic acid within serum or liver tissue. Treatment is dependent on identification of the viral pathogen. Herpes simplex and varicella zoster are treated with acyclovir, whereas CMV is treated with ganciclovir or foscarnet. Epstein-Barr virus–induced donor lymphocytes have been used to treat Epstein-Barr virus–associated lymphoproliferative disorders after allogeneic bone marrow transplantation.[129]

Fungal involvement of the liver is often seen in conjunction with widespread dissemination. There may be granulomas, abscesses, cysts, fungus in biliary ducts, or infarcts from vascular occlusion. Typically, *Candida* species are seen; however, any fungal pathogen can occur. Fungal infection often presents with right upper quadrant abdominal pain. Workup then discovers positive serum tests for fungal antigens or DNA, radiologic findings of fungal infection, and, if necessary, histology (including special stains).[127,130] If there is a suspicion of active infection in the liver, liposomal amphotericin, voriconazole, or caspofungin should be given until engraftment is established.[127,131] Bacterial infections of the liver occur less commonly but present similarly.

Gallbladder stones from poor oral intake, cytoreductive therapy causing exfoliation of gallbladder mucous-containing cells, and increased biliary excretion of precipitable material (cyclosporine A [CSA], antibiotics) all contribute to a 70% incidence of gallbladder sludge.[132,133] Sepsis can also lead to cholestasis and hyperbilirubinemia. This is mediated by endotoxins, interleukin 6 (IL-6) and TNFα.[127,134] Rarely, persistent biliary obstruction can be caused by lymphoproliferation from EBV or CMV-related biliary disease, duodenal hematoma as a complication of endoscopy, inspissated biliary sludge, or leukemic relapse in the head of pancreas.[127,135] Numerous medications required for HCT can have direct toxicity on the liver, including antibiotics, fluconazole, and CSA. Histologically, drug effect should be suspected when there is significant hepatocellular necrosis and minimal inflammation.

Veno-occlusive disease (VOD) after allogeneic HCT was first reported in 1979[136] and now is recognized as a major cause of morbidity and mortality in the first 100 days of transplant. The disease process begins in the sinusoids due to endothelial injury and affects venules only late in the course of the disease.[127] The pathogenesis is believed to result from hepatic venule and sinusoidal endothelial injury.[137] Histologically, subendothelial edema, endothelial cell damage with microthrombosis, fibrin deposition, and expression of factor VIII and von Willebrand factor within venular walls are seen.[138] Hepatic necrosis occurs, and collagen deposition in the sinusoids, venular wall sclerosis, and collagen deposition in the venular lumen are seen as the disease progresses.[139] Risk factors can include elevated transaminases before the conditioning regimen,[140-142] age <6 to 7 years,[143] use of methotrexate for GVHD prophylaxis,[144] presence of oral mucositis,[145] interstitial pneumonitis,[146] or transfusional iron overload.[147] Certain preparative regimens have also been found to have a higher incidence of VOD, including those with high doses of total body irradiation, cyclophosphamide, or the combination of busulfan and cyclophosphamide, or etoposide and carboplatin.[141,142,148,149] A trial of adults undergoing HCT using everolimus and sirolimus for GVHD prophylaxis was terminated prematurely because of an unacceptably high rate of severe VOD and

thrombotic microangiopathy.[150] The authors felt that busulfan use in conditioning may have been a contributing factor.

Clinically, VOD presents with hyperbilirubinemia, painful hepatomegaly, and fluid retention. The incidence varies based on risk factors and the criteria used but reportedly are as high as 55%,[140] with mortality rates ranging from 3% to 67%.[151] Significant variability in mortality results from differing conditioning regimens and definitions of VOD. Two sets of criteria have been used for VOD. Jones and associates[141] first described VOD and modified this criterion as hyperbilirubinemia greater than 2 mg/dL within 21days of transplant with at least two of three other findings: hepatomegaly, ascites, or 5% or greater weight gain. McDonald and colleagues[140] in Seattle defined VOD in their series as two of the following criteria occurring within 20 days of transplant: hyperbilirubinemia greater than 2 mg/dL, hepatomegaly or right upper quadrant pain, or sudden weight gain greater than 2% of body weight. Clinically, most patients with VOD develop symptoms between days 6 and 7 after transplant, peak around 10 days after onset, and return to baseline 10 days later if they are going to recover.[141] Multiorgan failure is seen more frequently in patients with VOD.[140,142] Pulmonary dysfunction, pleural effusions, hepatorenal syndrome, sodium retention with subsequent edema, and congestive heart failure all can occur and contribute to the high mortality rate. Liver ultrasound with Doppler study showing reversal of portal flow is a late finding in VOD[143] but is not part of the diagnostic criteria. Liver biopsy can be performed to diagnose VOD, but it is recommended that it be reserved for patients in who the diagnosis is uncertain and other diagnoses must be excluded such as hepatic GVHD.[152]

In some patients it is difficult to differentiate between VOD and hepatic GVHD, and more invasive procedures are needed. Transvenous liver biopsy and hepatic venous pressure gradient measurements can be performed safely[153] and have been found in a limited setting to have predictive value, with a hepatic venous pressure gradient greater than 30 mm Hg associated with poor outcome.[154] Hepatic venous pressure gradient levels greater than 10 mm Hg have been shown to be highly specific for diagnosis of VOD.[155,156]

Given that the pathogenesis of VOD is thought to involve endothelial injury and coagulation factor deposition, attempts have been made to reduce the hypercoagulable state with several agents, including heparin, prostaglandin, and bile salts. A systematic review and meta-analysis by Imran and coworkers[157] evaluated 12 studies using low-molecular-weight heparin or unfractionated heparin as prophylaxis for VOD and found that the decrease in risk of VOD was statistically not significant. A prospective study compared antithrombin III in 91 children to 71 historic controls and reported no significant difference in the incidence between the two groups.[158] Ursodiol in historical studies and randomized trials has been shown to cause mild to moderate reduction in VOD occurrence.[159,160] More promising is the use of defibrotide for prophylaxis, and several studies have been published describing its efficacy.[161-163] A phase 3 randomized controlled, multicenter trial published in 2012 showed a lower incidence of VOD (12% versus 20% p value of 0.05) and VOD-associated renal failure with no difference in the risk of hemorrhagic events.[164] The joint working group by the hemato-oncology subgroup of the British Committee Standards in Hematology (BCSH) and the British Society for Blood and Marrow Transplantation (BSBMT) published guidelines in 2013 recommending (strength 1A) the use of defibrotide for the prevention of VOD in children with

specific preexisting risk factors.

N-acetylcysteine, a thiol antioxidant, and nitric oxide have been tried in anecdotal reports as treatment for VOD.[165,166] Thrombolytic therapy with recombinant tissue plasminogen activator has been used successfully.[167,168] However, this is accompanied by the risk of bleeding, with one of these studies reporting an 88% incidence of bleeding and 28% incidence of severe bleeding.[167] Defibrotide has been evaluated in phase II trials showing 30% to 60% remission rates, even in patients with severe VOD.[169] A multicenter prospective study of 333 patients published as an online abstract showed a statistically improved outcome in complete response to defibrotide treatment (29% versus 9%, $p = 0.0019$) and D+100 survival (49% versus 25%, $p = 0.0016$) compared with historical controls (303 subjects had received HCT, whereas 28 were non-HCT patients who developed VOD). There was an 18% incidence of bleeding with a 2% incidence of life-threatening hemorrhage with defibrotide therapy in these patients. Due to the risk of hemorrhage, defibrotide therapy requires close monitoring.[170] There is currently a multicenter study in the United States of defibrotide for patients diagnosed with VOD. The study is titled "Defibrotide for Patients with Hepatic Veno-occlusive Disease: A Treatment IND Study."[171] Defibrotide is no longer available in the United States for compassionate use. Further work is required to investigate the optimal dose and route in the treatment of these patients. The joint working group by BCSH/BSBMT also recommended the use of defibrotide in treatment of VOD in children (strength 1B).[152] Supportive treatment for fluid retention and multiorgan failure is an important part of management of these patients.

Colitis and Other Gastrointestinal Complications

Gastrointestinal (GI) complications that arise after transplantation often result from mucosal damage secondary to radiotherapy and chemotherapy regimens, together with immunosuppression following transplant.[172] Upper GI complications include diffuse mucositis, nausea, vomiting, and nonspecific abdominal pain. Barker and colleagues reported a 90.1% incidence of mucositis and an 85.2% incidence of posttransplant vomiting in a retrospective study of 142 patients who underwent HCT.

Lower GI/intestinal acute complications include *C. difficile* colitis, viral and other gastroenteritis, typhlitis, intestinal GVHD, and intestinal thrombotic microangiopathy.[173] In this case series, *C. difficile* colitis was seen in 8.5% of patients, viral enteritis in 7.0%, typhlitis in 3.5%, and intestinal GVHD in 27.4%.[173] The incidence of typhlitis in this series was much lower than the 32% incidence previously reported in the literature for AML patients.[174]

Viruses such as CMV, adenoviruses, and rotaviruses can cause diarrhea in the immediate posttransplant period. Imaging findings include nonspecific bowel wall thickening, ascites, and adjacent inflammatory change especially in the ileocecal region.[172]

Neutropenic enterocolitis or typhlitis is a necrotizing inflammation of the colon in an immunocompromised patient. There is a predilection for the cecum, thought to be due to the marked distensibility of the cecum along with lower vascularity. The clinical manifestations are a triad of abdominal pain/tenderness, fever, and neutropenia.[172] The incidence of typhlitis can vary depending on the aggressiveness

of chemotherapy and prophylactic antibiotics used.[175] The typical time frame to be diagnosed with typhlitis, after HCT, appears to be around 15.5 ± 7 days.[175] Plain x-ray or ultrasounds of the abdomen appear to be good initial imaging modalities. CT scan can be utilized if the diagnosis is questionable with initial imaging. Plain x-ray of the abdomen will likely show dilation of small bowel loops with a paucity of gas in the right side of the abdomen. In advanced cases with perforation, one may see free intraabdominal air. Ultrasound of the abdomen will likely show asymmetric, echogenic wall thickening of the cecum and terminal ileum. If utilized, CT will show luminal narrowing and stranding in the pericecal fat.[172] Management includes bowel rest, antibiotic coverage to include gram-negative organisms, G-CSF to treat neutropenia, and providing optimal parenteral nutrition. Consideration for antifungals should be considered if there is no clinical improvement on initiation of antibiotics. Persistent GI bleeding despite resolution of neutropenia and coagulopathy, evidence of perforation with peritonitis, and uncontrolled sepsis are potential surgical indications.[174]

Pneumatosis intestinalis can be seen in typhlitis, in which case it implies imminent bowel perforation.[172] Corticosteroid therapy appears to be a significant factor, inducing atrophy of the Peyer patches in the intestine with resultant mucosal defects and dissection of intraluminal air into the submucosal or subserosal regions. If detected in an asymptomatic patient it will most often be resolved with conservative management.[172,176]

Intestinal acute GVHD usually develops after 3 to 5 weeks and can be accompanied by skin and hepatic GVHD. Chronic GVHD occurs several months after transplantation.[177,178] Symptoms include secretory diarrhea, fever, nausea, vomiting, abdominal pain, and intestinal hemorrhage.[179] CT in addition to nonspecific findings may show bowel wall enhancement correlating with mucosal destruction and replacement with granulation tissue.[172]

Thrombotic microangiopathy (TMA) of intestines can occur after HCT and is caused by intimal injury to the microvasculature followed by formation of microthrombi. The injury is presumed to be due to chemotherapy, total body irradiation or pretransplant conditioning regimen, and the addition of drugs known to be associated with this disease such as tacrolimus and cyclosporine A. This is a rare complication but can mimic GVHD by presenting with fever and refractory diarrhea. Laboratory findings include elevated LDH and fragmented erythrocytes on a peripheral blood smear. Treatment is challenging and often requires removal of the possible offending immunosuppressant medication. Daclizumab has shown some promising results in experimental studies.[180]

Pancreatitis can also be seen in HCT patients. Barker and colleagues reported a 4.9% incidence of pancreatitis. This was not associated with any specific induction chemotherapy regimen.[173] Werlin and associates reported a similar 3.5% incidence of pancreatitis and recommended testing for pancreatitis prior to attributing GI symptoms to mucositis.[181]

Myelosuppression and Hematologic Complications

Myelosuppression and Immune Dysregulation

Stem cell transplant conditioning results in an extended period of neutropenia, anemia, and thrombocytopenia. Neutrophil engraftment is defined as an absolute

neutrophil count (ANC) of greater than or equal to $0.5 \times 10^3/\mu L$ on 3 consecutive days following the postconditioning nadir. Neutrophil engraftment typically occurs 2 to 4 weeks following stem cell infusion. The duration of time from stem cell infusion to engraftment depends on numerous transplant-related factors.[182] When peripheral blood progenitor cells are used, engraftment typically occurs 1 to 6 days sooner than when bone marrow is used as the stem cell source.[183] Engraftment occurs slower when umbilical cord blood is used compared to PBSC and bone marrow.[184] Granulocyte stimulating factors are commonly used following autologous HPT and umbilical cord blood transplant to reduce the time to neutrophil engraftment.[185] Platelet engraftment generally occurs 1 to 2 weeks following neutrophil engraftment but can take weeks to months. A platelet count less than 100,000 on day 100 following transplant is associated with poor outcome.[185]

Neutrophil engraftment does not signify the reconstitution of a fully functional immune system. It is crucial to remember that engrafted post-HCT patients remain significantly immunocompromised and are at risk for life-threatening opportunistic infections. The restoration of normal immune function can take as long as a year in patients without significant post-HCT complications and longer in patients with chronic GVHD.[186] Typically, natural killer cell recovery takes approximately 1 month and T-lymphocyte recovery takes 6 to 12 months.[187] Restoration of normal B-cell function takes approximately 3 to 6 months in the absence of GVHD.[188]

Infectious Complications

Patients undergoing HCT have increased susceptibility to infection because of a combination of (1) neutropenia, (2) breakdown of physical barriers (mucositis, indwelling venous catheters, skin lesions), and (3) defects in cellular and humoral immunity as a result of the conditioning regimen and immunosuppressive therapy given. The susceptibility to any particular organism varies according to the stem cell source (for example, umbilical cord blood recipients are at increased risk for viral infection) and over the course of the transplant period. During the first 2 to 4 weeks of the posttransplant period while the patient is neutropenic, bacterial infections account for approximately 90% of the infections. Enteric gram-negative bacilli (eg, *Escherichia coli*, *Klebsiella, Enterobacter, Pseudomonas aeruginosa*) can cause rapid hemodynamic instability. The gram-positive infections (*Staphylococcus* and *Streptococcus*) are frequent causes of infections when central venous catheters are present. Therefore empiric antibiotic coverage for fevers during this time must be broad spectrum and provide adequate coverage for these organisms.[189-191]

Fungal infections are increasing in frequency with better treatment and prophylaxis of bacterial and viral infections, particularly after allogeneic transplantation. Fungal pathogens in HCT patients include the yeasts (eg, *Candida* spp., *Cryptococcus neoformans*), molds (eg, *Aspergillus, Fusarium, Mucormycosis*), and dimorphic fungi (eg, *Coccidioides, Histoplasma, Blastomyces*). Of these, *Candida* and *Aspergillus* are most common. *Candida* spp. colonize the gastrointestinal tract in more than half of healthy people,[192] but they become opportunistic infections in HCT patients.

Candidal infections can occur as superficial mucosal infections (eg, thrush) or deeply invasive (hepatosplenic candidiasis). Esophageal candidiasis is associated with dysphagia and retrosternal pain. This may be difficult to distinguish from

chemotherapy or radiation-induced mucositis or herpetic mucositis. Endoscopy may be necessary to diagnose and appropriately treat. Candidemia may present with fever and systemic symptoms and is frequently not associated with tissue involvement. Because many HCT patients receive fluconazole prophylaxis, candidemia should be treated with amphotericin B. Traditionally, patients with documented candidemia or persistent/recurrent fevers should have undergone evaluation for multiorgan involvement, including CT or magnetic resonance imaging (MRI) of the brain, chest, and abdomen, and an ophthalmologic examination. However, given that more attention is being focused on the radiation risk of CT for the development of future cancers and the improvement in antifungal prophylaxis, the use of abdominal and pelvic CT scans as screening tools (not in cases of documented fungemia) for invasive fungal disease is now being called into question. A quality improvement project from St. Jude Children's Research Hospital showed very low yield of abdominal CT in detecting undiagnosed fungal infections in patients with prolonged fever and neutropenia.[193] The group recommends that routine abdominal CT as a screening tool for invasive fungal disease no longer be performed. Instead they recommend ultrasound or limited MRI in patients with clinical suspicion for invasive fungal disease in the abdomen.

Aspergillus spores are routinely inhaled and in immunocompromised or HCT patients can cause invasive infections. Neutropenia and GVHD with immunosuppressive treatment are risk factors for this. Outbreaks of aspergillus can occur in areas of construction or with contaminated ventilation. Invasive aspergillosis occurs most commonly in the lungs with fever, cough, dyspnea, and ultimately hemoptysis as the disease progresses. The characteristic radiographic appearance is a cavitary lesion, but nodular infiltrates and bronchopneumonia are also seen.[194] BAL should be performed initially. However, up to 50% of patients have a negative BAL, and open-lung biopsy should be considered if suspicion remains after a negative BAL.[195]

CMV is one of the most problematic viral infections for HCT patients posttransplant. CMV may emerge in the allogeneic patient between 1 to 3 months posttransplantation if either the patient or donor was CMV positive before transplant. CMV lays dormant after the initial clinical infection. However, in immunosuppressed patients, this virus can reactivate and result in interstitial pneumonitis, enteritis, encephalitis, retinitis, or bone marrow suppression. CMV infection is defined as the identification of CMV from any site or the seroconversion to CMV positivity on PCR or antigenemia testing. CMV disease is defined as the clinical manifestations seen in the presence of CMV infection. The use of CMV-negative blood products and leukofiltration of blood products along with routine screening during the first 100 days posttransplant with PCR or antigen testing has helped reduce the risk of CMV infections in patients undergoing transplant. Monitoring of CMV with antigenemia testing and PCR testing is the standard of care for 100 days posttransplant and allows for preemptive therapy if results of these tests become positive before onset of clinically apparent disease. Ganciclovir, valganciclovir, or foscarnet treatment is then given for 7 to 14 days followed by prophylaxis or screening through 100 days posttransplantation.[196] Interstitial pneumonitis from CMV presents with hypoxia and fever and an interstitial pattern on chest x-ray film. Untreated, there is an 80% mortality rate.[197] Ganciclovir and intravenous (IV) immunoglobin are the recommended treatments for CMV

interstitial pneumonitis.[198] Ganciclovir is dosed at 10 mg/kg daily for 21 days followed by 5 mg/kg/day 5 days per week until day 180 posttransplantation. IV immunoglobin is given at 500 mg/kg every other day for 21 days, followed by 500 mg/kg weekly until day +180. With this regimen, survival is 80%. For patients resistant to ganciclovir or unacceptable medication toxicity, foscarnet may be given at 60 mg/kg three times daily for 7 days, then 90 mg/kg/day until day +180.[17,199] Ganciclovir can cause neutropenia, and administration of growth factor (eg, G-CSF, granulocyte macrophage–CSF) should be considered if the absolute neutrophil count falls below 1000/uL. If the absolute neutrophil count falls below 500/μL, holding the drug should be considered. In addition, renal adjustment may be necessary, as both ganciclovir and foscarnet can be renal toxic. CMV prophylaxis with ganciclovir is prohibited by its marrow-suppressive effects.

CMV enteropathy presents with dysphagia, abdominal pain, nausea, vomiting, diarrhea, or gastrointestinal bleeding. These symptoms can be seen with GVHD as well, and endoscopy should be performed to aid in the diagnosis. Treatment is similar to that of CMV pneumonia.

EBV, HHV6, herpes simplex virus, adenovirus, varicella-zoster virus, human metapneumovirus, and BK virus infections are all common posttransplantation and cause a range of clinic findings including hemorrhagic cystitis, colitis, retinitis, encephalitis, and pneumonitis. The diagnostic and treatment options for each of these viruses and clinical presentations are beyond the scope of this chapter. The reader is referred to multiple published reviews of this topic.[200-204]

Study has focused on the role of adoptive transfer of virus-specific T cells from seropositive donors. Translational and clinical research have focused on the role of this immunotherapeutic approach to the treatment of CMV, EBV, and adenovirus. Broad application of this biotechnology is evolving.[205-207]

Graft Failure

Graft failure is an uncommon, potentially lethal complication of HCT. Primary graft failure is defined as failure of the stem cell graft to recover hematopoietic function by day 30, though some patients successfully engraft later than day 30. Secondary graft failure is the loss of the donor stem cell graft after initial engraftment. The risk of graft failure is increased with HLA-disparity between donor and host, when reduced-intensity conditioning regimens are used, with the use of umbilical cord blood stem cells, and when transplant is performed for a nonmalignant hematologic condition.[208] It is rare in HLA-matched sibling donor transplants. Graft failure is treated with the infusion of hematopoietic cells either alone or in combination with growth factors, chemotherapy, or immunosuppression.[209,210] Graft failure is an emergency as the risk of death increases with the duration of neutropenia and because there are few effective therapies.

Hematologic Complications

HCT recipients commonly require frequent blood product transfusions during the acute transplant phase due to conditioning-associated myeloablation and potentially increased consumption of platelets and RBCs. For most patients, the need for blood product transfusions declines rapidly following engraftment and hospital discharge.

However, some patients need transfusion support for months after transplant. All blood products should be gamma-irradiated to rid the product of competent donor T-cells that can cause transfusion-associated GVHD.[211] Additionally, blood products must be CMV negative to prevent transmission of the virus to nonimmune patients. This can be achieved by using blood from CMV seronegative donors or with leukofiltration.[212]

There is no commonly accepted standard transfusion parameter for either packed RBCs or platelets (see also Chapter 93). Studies have investigated the use of a platelet transfusion threshold of 10,000. Most studies have found the use of this lower trigger safe for nonbleeding patients, but it is not supported in all studies.[213-216] A Cochrane review of prophylactic transfusion at thresholds of $10 \times 10^3/\mu L$, $20 \times 10^3/\mu L$, and $30 \times 10^3/\mu L$ was reported.[217] The review found no difference in mortality rate or severe bleeding events among the groups. Similar studies are needed to assess the transfusion parameters of RBCs. Although transfusion parameters can be clinically useful, they do not replace clinical judgment.

Donors and recipients who are HLA matched are not necessarily ABO matched. ABO matching is not required for successful transplant and is a secondary consideration when choosing a donor. However, ABO mismatching puts the recipient at risk for immune-mediated hemolytic anemia. The risk for and severity of the potential hemolytic anemia depends on the degree of compatibility and is divided into four groups: (1) ABO-matched; (2) minor ABO mismatch, in which there is potential for hemolysis of the recipient RBCs by donor isoagglutinins (eg, donor blood type O+ and recipient A+); (3) major ABO mismatch, in which case the recipient isoagglutinins are directed against donor RBCs after engraftment (eg, donor blood type A+ and recipient O+); and (4) bidirectional mismatch, which combines minor and major ABO mismatch (eg, donor blood type A+ and recipient blood type B+).[218] When there is a major or bidirectional mismatch, the stem cell product must be RBC depleted or the patient must have the offending isoagglutinins removed by pheresis prior to infusion to prevent a hemolytic reaction. Minor incompatibility, in which the recipients RBCs are incompatible with components of the donor's plasma, puts the recipient at risk for an immune-mediated transfusion reaction. Plasma depletion of the product prior to infusion reduces the risk. Even when plasma depletion is used, mild hemolysis can exist for weeks to months due to antibody production from newly produced B lymphocytes against residual recipient RBCs.

There are many described late hemolytic complications of transplant, and most are uncommon. Autoimmune hemolytic anemias, thrombocytopenia, and neutropenias from post-HCT immune dysregulation can occur months to years after transplant and are typically managed with immune suppression, immune modulation, or IV immunoglobin.

Post-HCT thrombotic microangiopathy (TMA) processes include hemolytic uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP).[219,220] Both are reported with increased frequency in patients who received calcineurin inhibitors as part of their GVHD prophylaxis regimen.

HUS is a potentially life-threatening, uncommon post-HCT complication. It presents with hemolysis and mild to moderate renal dysfunction at a median time of 5 months post-HCT.[221] Patients may also have seizures and hypertension. Many cases of post-HCT HUS gradually self-resolve, although patients may be left with

residual renal dysfunction. Post-HCT TTP classically presents earlier than HUS with thrombocytopenia, schistocytes on the peripheral blood smear, and elevated LDH. Endothelial damage from transplant conditioning, GVHD, and calcineurin inhibitors is thought to contribute to the development of post-HCT TTP.[222] It differs from classic TTP of childhood in that ADAMTS13 deficiency is not present.[220,222] Additionally, standard therapies for idiopathic TTP, such as plasma exchange, do not appear to be effective for the treatment of post-HCT treatment. The role of eculizumab in posttransplant TMA is currently investigational, but it may be helpful.[223]

Iron Overload

Iron overload has been recognized as an important transplant complication as well as a risk factor for the development of other transplant-related complications.[224] HCT patients are at risk for increased iron burden due to repeated blood transfusions pre- and post-HCT and disturbed iron metabolism.[224,225] Adverse effects from iron overload may include increased susceptibility to infection, VOD, chronic liver disease, and cardiac dysfunction.[1,161,226] Studies show that iron overload has an adverse impact on survival in patients undergoing HCT for beta-thalassemia major and hematologic malignancies.[225,227,228] However, it is less clear what impact iron overload has on the risk for transplant-related toxicities in patients transplanted for other reasons.[229]

There are multiple ways to diagnose iron overload. Liver biopsy remains the gold standard, but frequently the diagnosis is made with imaging and laboratory studies. The serum ferritin is elevated in iron overload. However, ferritin is a nonspecific marker of inflammation that makes this a sensitive but not specific indicator of iron overload. Serum iron studies are useful adjuncts for diagnosis and are often used when monitoring the efficacy of therapy. MRI can provide a quantification of organ specific iron burden.[230] Phlebotomy is a standard treatment for iron overload.[231,232] However, it may have limited utility given that many patients may be anemic after HCT. Iron chelation is effective but limited by the practical considerations in the case of deferoxamine infusion and potential toxicities of the treatments.[233]

Graft-Versus-Host Disease

GVHD is the most common complication of allogeneic HCT. GVHD develops when donor T lymphocytes respond to proteins on recipient cells.[234] Activated donor T lymphocytes, monocytes, and macrophages trigger a self-propagating cycle of cytokine production and inflammation.[234,235] GVHD was historically categorized by the time of occurrence following transplant, with acute GVHD diagnosed if symptoms developed before day 100 or chronic if the presentation was after day 100. The traditional definitions of acute and chronic GVHD do not fully address the pathophysiology of the diseases and have evolved. The current National Institutes of Health (NIH) consensus recommends classification based on the clinical presentation rather than posttransplant day.[236] This classification recognizes two main categories of GVHD—acute and chronic—each with subcategories. Acute GVHD includes classic acute GVHD that develops within 100 days after transplant and persistent, recurrent, or late-onset acute GVHD that clinically resembles acute GVHD but occurs greater than 100 days after transplantation. Chronic GVHD includes classic

chronic GVHD occurring greater than 100 days after HCT with manifestations specific to chronic GVHD and an overlap syndrome, which has features of chronic GVHD and features typical of acute GVHD.[236] A follow-up NIH consensus conference has been convened and further change in definitions may be recommended.

The skin, gastrointestinal tract, and liver are the most common involved systems in acute GVHD. The cutaneous presentation is typically an erythematous maculopapular rash, although there are various possible skin findings. Diffuse bullous lesions with skin sloughing are the most severe manifestations of cutaneous GVHD. Acute gastrointestinal GVHD is characterized by diarrhea that is often bloody, may contain tissue, and is accompanied by severe abdominal pain and cramping. Hepatic acute GVHD typically presents with a cholestatic pattern of elevated bilirubin and alkaline phosphatase. Isolated transaminase elevation is uncommon. Less common presentations of acute GVHD are oral inflammation with possible ulceration and ocular inflammation. Acute GVHD is graded according to severity of the systems involved (Table 95.3).

TABLE 95.3

Consensus Criteria for Clinical Staging and Grading of Acute Graft-Versus-Host Disease

Skin	Liver	Gut	
Stage			
1	Rash[1] <25% or persistent nausea[2]	Bilirubin 2-3 mg/dL[3]	Diarrhea >500 mL/day[4]
2	Rash 25%-50%	Bilirubin 3-6 mg/dL	Diarrhea >1000 mL/day
3	Rash >50%	Bilirubin 6-15 mg/dL	Diarrhea >1500 mL/day
4	Generalized erythroderma with bullae	Bilirubin >15 mg/dL	Severe abdominal pain with or without ileus
Grade[5]			
I	Stage 1-2	None	None
II	Stage 3 or	Stage 1 or	Stage 1
III	—	Stage 2-3 or	Stage 2-4
IV	Stage 4 or	Stage 4 or	Stage 4[6]

[1] Use rule of nines or burn chart to determine extent of rash.

[2] Persistent nausea with histologic evidence of graft-versus-host disease in the stomach or duodenum.

[3] Range given as total bilirubin. Downgrade one stage if an additional cause of elevated bilirubin can be documented.

[4] Volume of diarrhea applies to adults. For pediatric patients, the volume of diarrhea should be based on body surface area. Downgrade one stage if an additional cause of diarrhea has been documented.

[5] Criteria for grading given as degree of organ involvement required to confer that grade.

[6] Grade IV may include lesser organ involvement with Karnofsky performance status <50%, so patients with stage 4 gut graft-versus-host disease usually are grade IV.

From Przepiorka D, Weisdorf D, Martin P, et al. 1994 consensus conference on acute GVHD grading. Bone Marrow Transplant. 1995;15:825-828.

The clinical presentation of chronic GVHD is more varied. The skin is the most commonly involved system. Patients may have persistent erythematous rash, severely dry skin, atrophy, changes in skin pigmentation, hair loss, or nail changes. The most severe clinical presentation of chronic cutaneous GVHD is sclerodermatous fasciitis. Chronic hepatic GVHD is clinically similar to acute hepatic GVHD. The differential diagnosis includes viral infection, iron overload, and medication toxicity. A liver biopsy can aid diagnosis, but it must be performed with

caution in patients with increased bleeding risk.[29]

In 2005, the NIH published a consensus paper defining chronic pulmonary GVHD as (1) biopsy-proved BOS or (2) BOS diagnosed by pulmonary function and radiologic testing in conjunction with chronic GVHD at an extrapulmonary site.[236] There is discussion in the literature that other late pulmonary complications such as BOOP, idiopathic pneumonitis, and late-onset diffuse alveolar hemorrhage may represent varied presentations of chronic GVHD. However, chronic pulmonary GVHD being manifested as anything other than BOS is not yet widely accepted.[110]

Gastrointestinal tract chronic GVHD may present as anorexia, nausea, vomiting, diarrhea, malabsorption, or weight loss. Other manifestations of chronic GVHD are sicca syndrome, oral scarring with salivary gland scarring, fasciitis, immune dysfunction, protein losing renal disease, and genitourinary scarring. Immune dysfunction independent of immunosuppressive medications is characteristic of chronic GVHD. Patients with chronic GVHD have abnormal splenic function and often need prophylaxis against encapsulated bacteria.[237]

GVHD prevention regimens differ between institutions and are chosen based on the donor and recipient pairing, underlying disease, stem cell source, recipient comorbidities, conditioning regimen used, and potential stem cell manipulation. Agents commonly used for prevention include cyclosporine, tacrolimus, methotrexate, rapamycin, mycophenolate mofetil, and corticosteroids. Depletion of the T-cell component of the stem cell graft effectively eliminates the risk of GVHD.

Corticosteroids are the mainstay of treatment for GVHD. Other upfront treatments that specifically target affected systems are oral dexamethasone and tacrolimus rinses and corticosteroid or tacrolimus topical therapies. There are many available second-line agents and treatment strategies for corticosteroid refractory GVHD, but none are considered standard. The choice of second-line therapy depends on the individual clinical situation. Due to prolonged treatment with corticosteroid, some patients with chronic GVHD are adrenally insufficient. When a patient with chronic GVHD needs intensive care, one should consider the use of stress dose hydrocortisone.

Neurologic Complications

Neurologic complications contribute significantly to the morbidity and mortality following HCT and are more common following HCT than in nontransplant oncology patients.[45,181,238,239] Seizures appear to be the most common clinical manifestation following HCT, occurring in approximately half of the reported cases of neurologic complications.[181,238] Other symptoms include encephalopathy, motor function deficits, cranial nerve palsies, visual disturbances, and impaired coordination.[45,181,238,239] In one account, encephalopathy was reported in 26 (6.4%) of 405 pediatric patients following allogeneic HCT.[239] In that report, the encephalopathy developed within the first 100 posttransplant days in all but one patient. Leukoencephalopathy was commonly reported in that study and others.[181,239-241]

Leukoencephalopathy primarily occurs in HCT patients who receive cranial radiation or intrathecal chemotherapy before and after transplantation. Clinically, this condition manifests days to months after transplantation and may present with dysarthria, ataxia, dysphasia, confusion, or decreased sensorium in severe cases. The white matter changes can be detected with either CT or MRI. Peripheral nervous

system neurotoxicity also occurs posttransplantation as an immune-mediated complication. Inflammatory degenerating polyneuropathy, myasthenia gravis, and polymyositis have all been described posttransplant.[242-244] These conditions present with muscle flaccidity, hypoactive deep tendon reflexes, and absence of extensor plantar reflexes.

Depending on the complications assessed, the length of follow-up time, and the patient population studied, clinical analyses report a wide range of neurologic complications in pediatric HCT patients with more recent studies reporting a range of 10% to 24%.[45,181,239,240,245,246] However, an autopsy study of both children and adults (age range, 1 to 48 years; average, 23.7 years) demonstrated neuropathologic abnormalities in more than 90% of patients who died after HCT.[247] In one pediatric report, 11 (10%) of 133 children experienced a life-threatening neurologic complication within the first 3 months following HCT.[245] In a more recent analysis, 40 (24%) of 165 pediatric HCT patients were found to experience neurologic complications.[181] In that study, neurologic complications were categorized as either (1) transient and nonrepetitive symptoms lasting less than 24 hours and without abnormalities on MRI or on CSF analysis or (2) persistent (lasting more than 24 hours) or repetitive symptoms associated with radiographic cerebral imaging or CSF analysis abnormalities. Nineteen (12%) of the 165 patients satisfied the criteria of the second group, approximating the incidence of the earlier study.

In that report, neurologic complications occurred most commonly in children who had undergone unrelated allogeneic transplantation (39%), more than related allogeneic transplants (21%) or autologous transplantations (11%). The finding of neurologic complications occurring more commonly in allogeneic rather than autologous HCT recipients has been previously noted.[240,248,249] These data support the finding that neurologic complications following HCT are related to the presence of GVHD and immunosuppression.[181,240,245,250-252] GVHD and the need for prolonged immunosuppression are clearly associated with many of the etiologies of neurologic complications in this patient population. Common etiologies of neurologic complications in these children include CNS infections, intracranial hemorrhage and stroke, metabolic disturbances, medication toxicity, and CNS involvement of the underlying disease.[181,238,239]

CNS infections are a consequence of neutropenia and immunosuppression. Depending on the time period after transplant, patients may develop bacterial meningitis, aspergillus invasion of the brain parenchyma and vessels, cerebral toxoplasmosis, or viral encephalitis. These CNS infections contribute significantly to the morbidity and mortality following HCT.[253] In addition to the association of GVHD with CNS infections, the medications used to treat GVHD are common causes of neurologic complications in this patient population. Neurotoxicity from CSA or tacrolimus can include tremor, seizures, headaches, cortical blindness, neuropathy, or mental status changes. Frequently, these symptoms are observed with levels above the therapeutic range, but this is not always the case. These effects usually are reversible with elimination of the drug. From 5% to 6% of HCT patients taking CSA may experience seizures.[254,255] Phenytoin, phenobarbital, or carbamazepine, often used to treat seizures, can alter cytochrome P-450 activity and interfere with CSA or tacrolimus levels. Valproic acid or levetiracetam may be a better alternative in this situation.[256-258]

Several chemotherapy agents that may be used in the HCT conditioning regimen

can have neurotoxicity. High-dose carmustine, frequently used for autologous transplants for Hodgkin disease or lymphomas, has been associated with seizures. Busulfan, frequently used in allogeneic transplants, can also cause seizures. In fact, phenytoin is often given prophylactically during busulfan administration. Levetiracetam may be a better alternative in this situation as well due to its lack of effect on cytochrome P-450 activity. Through phenytoin's induction of cytochrome P-450, it can alter busulfan metabolism (which is also metabolized through cytochrome P-450) lowering the patient's exposure to busulfan and potentially increasing the risk of relapse.[257,258]

CSA and tacrolimus are associated with the posterior reversible encephalopathy syndrome (PRES) seen in HCT patients.[181] PRES is a clinical entity that presents with headache, mental status changes, visual disturbance, and seizures. Neurologic imaging shows subcortical vasogenic edema preferentially involving the posterior regions of the brain. This syndrome is not unique to HCT patients and can be seen in patients with acute hypertension, preeclampsia, and renal disease (see also Chapter 94).[259] Treatment includes control of blood pressure, management of seizures, and replacement of calcineurin inhibitors such as tacrolimus or CSA with a different class of immunosuppressive agent.[259] If appropriately recognized and promptly treated, the neurologic changes in PRES are reversible. However, it is worth mentioning that this entity can present with life-threatening complications such as cerebral hemorrhages, cerebellar herniation, hydrocephalus, and status epilepticus.[260]

CSA, tacrolimus, and chemotherapeutics may also cause renal wasting of magnesium resulting in hypomagnesemia and lowering of the seizure threshold. In addition to hypomagnesemia, other metabolic abnormalities may occur in this setting, contributing to seizures. Moreover, metabolic derangements resulting in encephalopathy are the most common neurologic complications following HCT with an incidence estimated to be as high as 37%.[261] A more recent pediatric analysis suggests that metabolic derangements remain a significant cause of encephalopathy after HCT but with a much lower incidence (14%) than this earlier study.[239] Hypoxia, ischemia, hepatic failure, electrolyte imbalance, and renal failure have all been found to be etiologies of these metabolic derangements resulting in encephalopathy. Idiopathic hyperammonemia can occur in patients after high-dose chemotherapy used in transplant conditioning regimens. Altered mental status and respiratory alkalosis with elevated plasma ammonia occur acutely. Left untreated, irreversible cerebral edema may result.

Neurovascular complications are not uncommonly reported as neurologic toxicities associated with HCT. Thromboembolic episodes, subdural hemorrhages, and intracerebral hemorrhages are common examples. Thrombotic thrombocytopenic purpura has also been reported as a cause of encephalopathy following pediatric HCT.[239] In one report, 2 (10%) of 21 children with a definitive diagnosis of encephalopathy following HCT were found to have TTP and 1 other (5%) had evidence of a stroke.[239] In that report, 1 (5%) of the 22 children with intracranial imaging was found to have a subdural hematoma, and 2 (10%) were noted to have infarctions. In another report, 2 (11%) of the 19 children with persistent neurologic symptoms (>24 hours) after HCT were diagnosed with intracranial hemorrhage.[181] In a study of patients receiving HCT or conventional chemotherapy alone in a pediatric oncology center, 9 (12%) of the 76 patients who experienced a neurologic complication were found to have a vascular event.[238]

Neurologic complications appear to portend a poor prognosis. Nearly 60% of the children with persistent/repetitive symptoms and either radiographic or cerebrospinal fluid abnormalities following HCT died, more than a third of them as a result of their neurologic complication.[181] In another study of 113 pediatric allogeneic HCT patients, children with a neurologic complication following HCT were significantly more likely to die than those who did not experience such a complication.[245] Thirty-three (32%) of 102 patients without a neurologic complication had died at 6 years of follow-up as compared with 10 (91%) of the 11 patients with a neurologic complication ($p < .001$). In another study, neurologic complications were also associated with a higher mortality among pediatric HCT patients, but only in the early posttransplant period.[240] Similarly, in the Associazione Italiana Ematologia Oncologia Pediatrica's prospective study of 636 pediatric patients transplanted for acute leukemia, CNS toxicity was associated with early treatment-related death.[45] In that report, severe CNS toxicity was related to a threefold increase in the risk of treatment-related death as compared with absent or mild toxicity ($p = 0.02$). However, in a logistic regression model of all organ toxicities, the relationship between CNS toxicity and early treatment-related death was not statistically significant (relative risk, 2.2; 95% confidence interval, 0.8 to 5.5; $p = .11$). Finally, in a study of encephalopathy after pediatric HCT, 17 (65%) of 26 patients died; 12 never recovered from their encephalopathy.[239] In that report, only 4 (15%) of the 26 patients experienced a full recovery of their encephalopathy.

Late Effects

A complete discussion of the late effects of HCT is beyond the scope of this chapter. However, some potential late effects are relevant to intensive care providers. Patients who have been treated with total body irradiation, focal lung radiation, and some chemotherapeutic agents are at risk for chronic lung disease, including pulmonary fibrosis, obstructive lung disease, and restrictive changes.[53] Post-HCT cardiac late effects include cardiomyopathy, congestive heart failure, and arrhythmia. Anthracycline chemotherapy is a primary cause of cardiomyopathy. Anthracycline-related cardiomyopathy is dose dependent, and treatment given before transplant contributes largely to the risk of developing cardiac dysfunction though radiation may also play a role. Cardiac late effects related to radiation include fibrosis, arrhythmia (related to fibrosis), and restrictive cardiomyopathy. Children who received radiation are at an increased risk for myocardial infarction and congestive heart failure.[262]

Nutritional Support in the Critically Ill Hematopoietic Progenitor Cell Transplantation Patient

HCT patients may begin their course in malnourished state, which could put them at risk for the development of micronutrient deficiencies during transplant.[263,264] Deficiencies of micronutrients including magnesium, phosphorus, zinc, selenium, vitamin E, vitamin D, and β-carotene have been described during conditioning.[263,265-268] HCT patients are also at significant risk for the development of severe mucositis

and vomiting, making oral enteral nutrition difficult. Standardized feeding protocols may improve the chances of enteral nutrition being successful. In a study of 79 pediatric HCT patients who were followed closely on an enteral nutrition protocol, the majority of patients could be successfully fed enterally. In this protocol, the patient's oral caloric intake was measured daily. When it fell below 75% of the recommended intake for 3 consecutive days, an nasogastric tube was inserted and enteral feedings initiated. Seventy-one of the 79 patients required only enteral nutrition to maintain weight, 5 patients required a combination of enteral and parenteral nutrition, and only 3 patients were fed by parenteral nutrition alone.[269] Enteral nutrition may be the preferred method of nutrition when possible, as there is evidence that patients fed enterally are at decreased risk for developing GVHD.[270-272]

A few studies have shown an association between micronutrient deficiencies and transplant complications. Low zinc levels during the transplant course were associated with more febrile episodes, longer duration of febrile episodes, and more positive blood cultures.[273] Persistently low vitamin D levels were associated with more severe GVHD.[268] Low vitamin D levels have also been associated with worse overall survival after HCT as well as increased risk of graft rejection and relapse.[274]

Biochemical markers of oxidative stress during conditioning have been seen in HCT patients. Decreased glutathione and α- and γ-tocopherol levels have been documented during conditioning.[275] Increased serum Fe levels and a decreased total radical trapping antioxidant parameter of plasma (a measure of antioxidant reserve) and linoleic acid concentrations have also been documented in HCT patients.[276]

There is also increasing evidence for oxidative stress in critically ill patients with sepsis, systemic inflammation, and lung injury—all common reasons for ICU admission of HCT patients.[277-283] Therefore it is likely that the critically ill HCT patient who has recently undergone conditioning may be under a significant amount of oxidative stress.

There are a handful of published trials of antioxidant supplementation during HCT. In one trial, 37 pediatric HCT patients were given ursodeoxycholic acid, vitamin E, folinic acid, and total parenteral nutrition with traditional amounts of vitamins, minerals, and trace elements. There was no control group. The main outcome of the study was the feasibility of patients taking oral supplements. Most patients tolerated the oral medications well, and the authors were able to prove feasibility. In these patients they also noted less mucositis, less hepatic toxicity, and a shorter time to engraftment in comparison to a historical control group.[284] Another group performed a double-blind, randomized, placebo-control trial of selenium supplementation to 77 adults undergoing HCT. The researchers were able to show improvement in selenium and glutathione peroxidase levels in the group receiving selenium supplements. Those receiving selenium supplements also had less severe oral mucositis as well as a shorter duration of mucositis.[285]

Although common sense dictates that some type of nutrition is good and prolonged lack of any nutrition would lead to death, little is known about the optimal nutrition for critically ill pediatric HCT patients[286] (see also Chapter 87). Critical illness and HCT cause significant oxidative stress. Therefore it is possible that critically ill HCT patients may benefit from specialized nutritional strategies that optimize antioxidant capacity. This is a field that begs for further study.

SECTION VIII

Gastrointestinal System

OUTLINE

CHAPTER 96

Gastrointestinal Structure and Function

David M. Steinhorn

"All the diseases begin in the gut" and "death sits in the bowel."

Hippocrates[1]

PEARLS

- The alimentary tract is responsible for mechanical and enzymatic degradation of nutrients, absorption of biochemical substrates, hormone regulation of substrate flow, separation of the external from internal environments, and excretion of waste.
- The pancreas exhibits both endocrine and exocrine functions. Four distinct cell types facilitate endocrine function: B cells, which secrete insulin; A cells, which secrete glucagon; D cells, which secrete somatostatin; and PP cells, which secrete pancreatic polypeptide.
- The liver is composed of hepatocytes, endothelial cells, Kupffer cells (reticuloendothelial cells), bile duct cells, hepatic stellate cells, and oval cells. It has a dual vascular supply derived from the hepatic artery branches of the celiac axis providing about 30% of the blood supply with the portal vein providing approximately 70%.
- Cells of the gut-associated lymphoid tissue (GALT) are organized into three compartments: diffusely scattered through the lamina propria, within the epithelium itself, and as an aspect of lymphoid follicles called Peyer patches.
- Bacterial translocation is defined as the migration of bacteria or bacterial products from the intestinal lumen to mesenteric lymph nodes or other extra intestinal organs, and represents a disruption of the normal host flora equilibrium that leads to a self-perpetuating inflammatory response and ultimately to infection.

Introduction

Whether from primary gastrointestinal (GI) disease, sequelae of surgery, or complications of systemic disease, restoration of hepatic and GI function are central to successful discharge from the pediatric intensive care unit (PICU). The GI tract subserves multiple functions beyond digestion that impact systemic immunology, endocrinology, and microbiology.[2] New insights into the role of gut innervation are emerging as well as the compelling importance of the intestinal microbiome in drug metabolism and host protection.[3,4] The interactions among the gut, liver, and lung and between the liver and kidneys have led to the view that the gut may play a role as an *engine* of multiple organ dysfunction[5-7] as well as a regulator of metabolic and immunologic homeostasis. This chapter provides a comprehensive overview of basic gastrointestinal and hepatobiliary function for clinicians dealing with critically ill children.

Intestinal Structure, Digestion, Absorption of Nutrients, Water, and Electrolytes[8]

The alimentary tract is responsible for mechanical and enzymatic degradation of nutrients, absorption of biochemical substrates, hormone regulation of substrate flow, separation of the external from internal environments, and excretion of waste. Its primary role is to alter nutrients to be compatible with the internal environment of the body.

The functional absorptive unit of the intestine consists of villi and crypts. The cells of the small intestine are separated from one another by specialized junctions that serve as gaskets to prevent back diffusion of material into the intestinal lumen. A mucus layer secreted by goblet cells in crypts separates enterocytes from direct contact with the luminal contents.

Stem cells in crypts produce enterocytes and other specialized epithelial cells that differentiate as they migrate up the villi, a process that takes 48 to 72 hours (Table 96.1). Mature villous cells live ~6 days and are covered by microvilli making up the brush border containing digestive enzymes and membrane-bound transport systems for nutrients and electrolytes. Villous tips are predominantly absorptive, whereas crypt cells are primarily secretory. Rotavirus infections cause villous loss resulting in small intestinal mucosa composed largely of crypts and immature villi, leading to malabsorption and osmotic diarrhea. Malabsorption of nutrients is another manifestation of villous injury as is seen in gluten-sensitive enteropathy. In patients with poor tissue perfusion, mucosal ischemia and diminished flow to villi lead to ischemic injury and sloughing of the epithelium with an associated loss of barrier and transport functions.

TABLE 96.1

Functional Unit of Intestine

Structure	Function
Enterocyte	Formed in crypts, migrate to villus over 2-3 days; life span 6 days
Villi	Absorption
Crypts	Secretion
Microvilli	Amplifies surface area, contains enzymes and transport systems

Water and Solute Transport Across Intestinal Epithelium

Surface area and integrity of intercellular junctions are the major determinants of water and solute flux across epithelium. Microvilli increase the luminal surface area up to 40-fold. Transport of solute and water across epithelium occurs either by active or passive transport or by facilitated diffusion (Table 96.2). The average luminal fluid input of the adult gut is about 9 L per day and is composed of oral intake and endogenous secretions. Approximately 8.8 L is absorbed, about 7 L in the small intestine and 1.8 L in the colon. Less than 0.2 L is excreted as a component of the normal stool output. When rapid changes in dietary intake or endogenous secretions occur, the intestinal mucosa can adapt transport functions to compensate for the changes. The loss of mucosal surface area through disease or surgical resection alters net flux of solute and water in the GI tract. Loss of specialized absorptive function may occur following loss of specific areas of gut. An example of this reaction occurs in the setting of resection of terminal ileum, with loss of ability to absorb bile acids and intrinsic factor. Malfunction of absorptive mechanisms may lead to a life-threatening loss of fluid and electrolytes.[9]

TABLE 96.2

Intestinal Transport Mechanisms[33-35]

Active	Against electrochemical gradient Saturable kinetics Requires ATP
Passive	Ionic specificity May be associated with transport of a nonelectrolyte Proceeds down electrochemical gradient Steady-state based upon concentration differences Displays first-order kinetics May occur by convection via osmotic or hydrostatic gradient
Facilitated diffusion	Saturable kinetics Substrate specific Depends on carrier molecules (glucose, amino acid)
Na^+-H^+ exchanger	1 : 1 exchange of Na^+ or K^+ for H^+
K^+-H^+ exchanger (colon)	(regulates intracellular pH, cell volume, growth)
Coupled transport (Na movement down electrochemical gradient)	Na-Cl Na-K-Cl co-transport Na-glucose co-transport
Acidosis	Na^+ and Cl^- absorption
Aldosterone	Ileal and colonic Na^+ and water absorption
Glucocorticoids	Na^+ and water absorption in colon
VIP, PGE_1	Electrolyte and water secretion by intestinal epithelia

PGE1, prostaglandin E1; *VIP*, vasoactive intestinal protein.

Nutrients consist of macronutrients, such as carbohydrates, protein, and lipids, and micronutrients including minerals, electrolytes, trace elements, vitamins, and other metabolic cofactors such as biotin and carnitine. Critical illness leads to reduced intake of all nutrients and important alterations in substrate requirements and utilization. The fasting state in a healthy individual is characterized by a conservation of lean body tissue and reduction in energy expenditure with a shift to fatty acids for energy sources. In contrast, critical illness is associated with an increased metabolic rate and gluconeogenesis in excess of that needed to maintain

serum glucose. Breakdown of lean tissue and peripheral oxidation of amino acids with increased ureagenesis leads rapidly to malnutrition as a result of so-called autocannibalism. These changes are mediated by the classic stress hormones including cortisol, catecholamines, and relative excess of glucagon versus insulin levels (see also Chapter 81). Additionally, children with burn injury, septic shock and systemic inflammatory response syndrome (SIRS), those on dialysis, patients with extremely short intestine, or those receiving catecholamines or neuromuscular blocking agents are at risk for ICU-associated malnutrition and myopathy.

Enteral nutrition is the preferred method of feeding for critically ill children.[10,11] Early transpyloric enteral nutrition is well tolerated in critically ill children and is not associated with an increased incidence of complications. Many skilled PICU nurses can reliably place transpyloric tubes at the bedside, and placement is confirmed by abdominal x-ray. Small-bowel feeding allows a greater amount of nutrition to be successfully delivered to critically ill children compared to gastric feeds but may not eliminate the risk of occult gastric contents aspiration.[12] The institution of a feeding protocol has been found to achieve goal feedings quickly and also improve the tolerance of enteral feedings in patients admitted to the pediatric intensive care unit (see also Chapter 87).

Digestion of Carbohydrates[13] (Box 96.1)

Dietary carbohydrates include monosaccharides (glucose and fructose present in fruits, sweet corn, corn syrup, and honey), disaccharides, (sucrose, maltose, and lactose), and the principal mammalian milk sugar. Polysaccharides, such as starch, are polymers of glucose and are abundantly present in wheat, grains, potatoes, peas, beans, and vegetables. Fiber consists of nondigestible complex polysaccharides of plant origin. This includes both water-insoluble and water-soluble fiber. The average American diet is 3 : 1 soluble to insoluble fiber, and this may be markedly altered by the diets fed to ICU patients. Insoluble fibers affect fecal bulk, whereas soluble fibers have viscous effects in the upper GI tract including delayed gastric emptying, decreased postprandial glycemic response, and constipating effect. Furthermore, indigestible fiber is now known to be an important source of nutrition for the microbiome of the gut.[14]

Box 96.1

Conditions Impairing Dietary Carbohydrate Uptake

- Disaccharidase deficiency (acquired or congenital)
- Pancreatic insufficiency
- Membrane-associated transporter defect

Carbohydrates are a major source of calories in healthy children and enter metabolic pathways via glycolysis and the Krebs cycle pathway. They may be stored as glycogen and lipids when ingested beyond momentary energy needs or converted to structural materials. A person's requirement for energy is highly dependent on activity level or, in hospitalized patients, the degree of hypermetabolism

accompanying illness. In critically ill patients, the maximal ability to utilize carbohydrates may be limited during periods of high physiologic stress as a result of unbridled gluconeogenesis.

In the critically ill patient and those receiving tube feedings, the mechanical impact of chewing and salivary enzymes is absent. However, the liquid or elemental nature of enteral formulas circumvents that issue. For infants receiving breast milk, mammary amylase facilitates starch digestion because of their low levels of endogenous salivary and pancreatic amylase.[15] Pancreatic amylase is the major enzyme of starch digestion resulting in short oligosaccharides, maltotriose, maltose, and α-limit dextrins. The amylase concentration in the duodenum becomes limiting in cases of pancreatic insufficiency (eg, severe cystic fibrosis or major resection) when amylase levels become less than 10% of normal.[16]

The enterocyte is incapable of absorbing carbohydrates larger than monosaccharides. Therefore, further hydrolysis to monosaccharides is performed by intestinal *brush border disaccharidases*. Lactase and sucrase are the most clinically relevant disaccharidases and are synthesized in the enterocyte with insertion into the apical brush border membrane. With the exception of lactase and occasionally sucrase, the disaccharidases are rarely rate limiting for complete carbohydrate digestion. Deficiencies of any of the disaccharidase enzymes, either acquired or hereditary, may result in carbohydrate malabsorption. This is characterized by osmotic diarrhea with elevated fecal reducing sugars, abdominal distention, and flatulence secondary to fermentation of undigested oligosaccharides by colonic bacteria. An example is congenital sucrase isomaltase deficiency, an autosomal recessive disorder that is associated with absence of sucrase and maltase.[17,18]

Carbohydrates are absorbed by simple diffusion of monosaccharides or via brush border–associated transport mechanisms. Glucose, galactose, and xylitol are transported with sodium by the Na^+/glucose cotransporter leading to movement of luminal sodium across the apical membrane, bringing with it glucose or galactose in a one-to-one molar ratio. Glucose-galactose malabsorption is a deficiency of this transport mechanism leading to neonatal onset of severe diarrhea.[19] The second mechanism is a non–energy-dependent facilitated transport system for fructose. The general intestinal transport mechanisms are summarized in Table 96.2. The capacity to absorb fructose is limited in most humans, and excess ingestion has been found to cause symptoms of carbohydrate malabsorption.[20]

Loss of the epithelium and brush border frequently leads to symptoms of carbohydrate malabsorption. Common clinical conditions include rotaviral gastroenteritis, inflammatory bowel disease, celiac disease, sprue, ischemia/hypoxia, bacterial overgrowth of the proximal gut as a result of either stasis or use of antacids, and malnutrition. Severe mucosal damage requires 7 to 10 days for recovery of brush border function. Several infant and enteral formulas rely on starch as a carbohydrate source to minimize reliance on lactase.

The digestion of carbohydrates is generally very efficient, ranging from 80% to 100% of absorption from starch depending on the source of the starch. Bacterial fermentation of fiber and undigested carbohydrates produces short-chain fatty acids, used as fuel by the enterocytes, as well as gaseous hydrogen and methane, contributing to the flatulence associated with increased dietary fiber and malabsorption syndromes.

Digestion of Proteins[13] (Box 96.2)

The GI tract processes exogenous proteins with great efficiency as well as recycling endogenous proteins such as digestive enzymes, mucus, sloughed cells, and plasma proteins that leak into the alimentary tract.[21] The enteral processing of proteins entails a digestive and transport phase.

Box 96.2

Conditions Impairing Dietary Protein Uptake

- Ineffective pancreatic protease secretion
- Abnormal epithelial transport

(Hartnup lysinuric protein intolerance)

In the digestive phase, gastric acid denatures complex proteins making them more susceptible to the actions of proteolytic enzymes. The chief cells of the stomach release pepsinogens that are converted to active pepsins under acidic conditions. The pepsins are endopeptidases that release relatively large peptides and are inactivated when the pH rises above 4 as the food enters the duodenum. The completeness of gastric proteolysis depends in part on the rate of gastric emptying, the pH of intragastric contents, and the types of protein ingested.[21] There is, however, no evidence that patients with achlorhydria or those receiving antacids, H_2 blockers, or both agents have impaired protein digestion. In addition to initiating protein digestion in the mature subject, pepsins act as milk clotting factors, which are important in the neonate for curd formation and provide bulk to the infant's stools.

Luminal digestion proceeds in the small intestine mediated by five pancreatic peptidases, which are secreted by the pancreatic acinar cells as proenzymes and activated by enterokinase and trypsin. Each peptidase possesses proteolytic activity at specific internal or external peptide bonds. Proteins are degraded typically into mixtures of one-third free amino acids and two-thirds peptides containing two to six amino acid residues, which are suitable substrates for the brush border peptidases. The brush border peptidases convert the oligopeptides into monopeptides, dipeptides, and tripeptides suitable for transport into the enterocyte.

In the transport phase, specific membrane-associated transport mechanisms exist for the uptake of amino acids and dipeptides. They involve *simple diffusion, facilitated transport,* and *carrier-mediated active transport* (see Table 96.2). Na^+ coupled active transport is an energy-dependent process associated with the uptake of luminal Na^+ and an amino acid (or glucose) and exchange of the sodium and associated molecule for K^+ through the basolateral membrane on the serosal side.[22] Peptide transport may also occur using an H^+/peptide transport protein, which moves according to an H^+ gradient in the acidic pH microclimate of the intestinal brush border. Na^+-H^+ exchange in the brush border and Na^+-K^+-ATPase in the basolateral membrane[23] maintain the necessary gradient. It is important to note that many amino acids are absorbed more rapidly as dipeptides than as free amino acids. This fact has been capitalized on in the development of enteral nutritional formulas for critically ill

patients because oligopeptide mixtures have a lower osmolarity and are more efficiently absorbed than single amino acid solutions of equal nitrogen content. Because of the efficient gastrointestinal absorption of dipeptides, patients with specific amino acid transport defects such as Hartnup disease (defective tryptophan transport) and lysinuric protein intolerance (defect in dibasic amino acid transport—lysine, arginine) infrequently have gastrointestinal symptoms related to dietary protein malabsorption and instead more commonly manifest with nongastrointestinal symptoms such as aminoaciduria.

Once inside the enterocyte, peptides are quickly degraded into their constituent amino acids by cytoplasmic peptidases. Only minute quantities of intact peptide and protein gain access to the systemic circulation. The cytoplasmic amino acids derived from digested proteins are a major source of free amino acids used directly by the enterocyte. When absorbed beyond cellular needs, the free amino acids are released to the portal venous circulation for hepatic and systemic use. Only 23% of absorbed amino acids will pass to the periphery without modification.[24] Of the remaining nitrogen, 57% is converted to urea with the carbon skeleton salvaged for synthesizing other substances, and 20% of the total ingested amino acids will be used directly for hepatic protein synthesis.

During periods of fasting, the enterocyte derives the majority of its nourishment from the mesenteric arterial vascular supply, whereas during digestion, the enterocyte derives a significant part of its nutrient requirements from the luminal contents. Experience with mucosal recovery and adaptation after injury reveals that an enteral route of nutrition permits optimal recovery.[25] In the premature infant and neonate, the small intestine is capable of absorbing intact milk proteins by pinocytosis. These proteins may include secretory immunoglobulins from breast milk as well as food antigens. Peptidase inhibitors have been demonstrated in colostrum and breast milk, partially explaining the failure of normal digestive mechanisms to degrade some of these complex dietary proteins. Both antibodies and antigens ingested with maternal milk create an important part of the immune repertory developed during early infancy (see later section on gut immunology). Although the exact time of "closure" of the intestinal mucosa to the uptake of macromolecules has not been defined in human infants, other mammals demonstrate marked intestinal impermeability to foreign proteins by the time of weaning from breast-feeding.

Digestion of Lipids[26] (Box 96.3)

Dietary fat accounts for approximately 50% to 70% of the nonprotein calories consumed by infants and ~30% of nonprotein calories consumed after age 2 years.[27] Dietary fat is ingested principally in the form of triglycerides containing the fatty acids palmitate and oleate (C16:0 and C18:1, respectively). Dietary triglycerides of animal origin predominantly contain long-chain (ie, longer than C14 chain length) saturated fatty acids. Polyunsaturated fatty acids are mostly of vegetable origin and include linoleic and linolenic acid, also referred to as essential fatty acids because of absent de novo synthesis in humans. Other dietary lipids include fat-soluble vitamins, cholesterol, prostaglandins, waxes, and phospholipids.

Box 96.3

Conditions Impairing Dietary Lipid Uptake

- Decreased bile salt pool in gut (biliary obstruction, short bowel syndrome)
- Impaired pancreatic secretions (pancreatic insufficiency, pancreatitis)
- Suboptimal pH in gut (gastric hypersecretion)
- Rapid transit time (short gut syndrome, diarrheal states)
- Mucosal diseases (celiac disease, inflammatory bowel disease, bacterial overgrowth)
- Impaired enterocyte function (abetalipoproteinemia)

In healthy adults, digestion and absorption of fat are complete with only 5% to 7% of ingested fat escaping absorption. Under normal physiologic conditions, healthy infants up to age 9 to 12 months fail to absorb 15% to 35% of dietary fat. Digestion and absorption of dietary fat are generally completed by the middle third of the jejunum; however, the presence of dietary fiber may reduce the rate and extent of absorption. Loss of dietary fat places children at significant risk for calorie and fat-soluble vitamin malnutrition.

Fat Digestion

Fat digestion begins with the formation of emulsions, which increase the surface area for enzyme interaction. Emulsification begins with the release of fat by mastication and gastric milling of chyme. Bile salts and coating by phospholipid derived from the diet result in a stable emulsion droplet with a hydrophobic center consisting of triglyceride, cholesterol esters, and diglyceride in a hydrophilic envelope. Mammary, lingual, and gastric lipases play an important role in direct lipolysis of long- and medium-chain triglycerides that are present in maternal milk.[28] Lingual and gastric lipases are active at pH <5 and begin digestion of fat in the stomach; however, overall they play only a limited role in the digestion of lipids. Intragastric lipolysis is consistent across all age groups.[29]

Most of the enzymatic degradation of dietary lipids to fatty acids and monoglyceride occurs by the action of pancreatic lipase and colipase, and it requires an alkaline environment (pH 6 to 8). This underscores the importance of secretion of bicarbonate by the pancreas and biliary tract in order to neutralize gastric acid. Colipase is an essential cofactor for lipase action. Colipase's role is to displace the bile salt-triglyceride interaction in emulsion droplets and micelles in order to facilitate lipase hydrolysis of the triglyceride. Triglyceride hydrolysis occurs at the interface between the emulsion droplet and aqueous phase within the lumen. This is a two-step process. The first step is the enzymatic hydrolysis of long-chain triglycerides and liberation of fatty acids from the glycerol backbone. The second step is formation of fatty acid micelles, which is most efficiently done with the aid of bile salts[30] to move the fatty acids across the unstirred water layer to the epithelium for absorption.

The transit through the unstirred water layer adjacent to the epithelial surface is

considered the rate-limiting step in lipid absorption. Brush border lipase enzymes are involved as well. The milieu of the unstirred water layer is acidic (pH 5 to 6) owing to the activity of the brush border membrane sodium-hydrogen (Na^+/H^+) exchanger. The acid environment facilitates dissociation of fatty acids from micelles resulting in a high concentration of fatty acids necessary for diffusion across the mucosal membrane.

Once inside the enterocyte, long-chain fatty acids and monoglycerides are resynthesized into triglycerides and packaged as chylomicrons. Lipoproteins (eg, apo-A, apo-B) and cholesterol are attached to the intestinal chylomicrons and confer important properties for the subsequent systemic uptake and metabolism of the chylomicrons. This process appears to be defective in cystic fibrosis and may account for some of the fat malabsorption seen in this disease.[31] The chylomicrons are exported into the intercellular space and transported through the intestinal lacteals to become part of the intestinal lymph. On entering the bloodstream through the thoracic duct, the chylomicrons are associated with other apolipoproteins that allow them to be recognized by specific peripheral tissues.[32]

Dietary lipids containing short- and medium-chain (C6-C12) triglycerides (MCTs) are handled differently from those of long-chain triglycerides. As much as 30% of MCTs may be absorbed intact into enterocytes by passive diffusion and enter the portal venous blood directly. MCTs are hydrolyzed by pancreatic and mammary lipases to fatty acids and monoglycerides and rapidly enter the enterocytes where they emerge into the portal venous system without reesterification as occurs with long-chain fatty acids.

Intestinal Lymphatics

The intestinal lymph *chyle* is composed of chylomicrons and lipoproteins secreted by the intestinal epithelium in the postprandial state together with nonresorbed interstitial fluid. Chyle follows the intestinal lymphatic channels along the mesentery and enters regional lymph nodes from which it flows cephalad through the thoracic duct and ultimately enters the central venous circulation. In the fasting state, intestinal lymph production is relatively low. It increases 20-fold during the active absorption of a typical meal. The intestinal chyle is joined by lymphatic drainage from other tissues including liver and pancreas. The protein content of chyle is 2.2 to 5.9 g/dL with a triglyceride content of 0.4 to 6 g/dL and 400 to 6800 lymphocytes/dL. During digestion of a meal containing long-chain fats, chyle has a typical milky white appearance because of the presence of chylomicrons. The rate of formation of chyle depends on the state of nutrient absorption, portal venous pressure, and the rate of lymphatic uptake. Conditions that create portal hypertension (eg, portal vein thrombosis, cirrhosis, congestive heart failure) or impair the flow of lymph back to the central circulation (eg, increased central venous pressure, superior vena cava syndrome) predispose to the collection of chylous ascites in the abdomen.

Regulation of Electrolyte and Water Movement[33-35]

The movement of water is primarily coupled to the movement of solute in the form of electrolytes and nutrients. It is largely passive, occurring through paracellular routes in the intestine coupled with solute movement. Expression of transporters involved in intestinal water and electrolyte transport is regionally defined in the

intestines. Electrolytes are taken up by enterocytes at the apical membrane and extruded through the basolateral membrane into the paracellular space. The relatively hypertonic paracellular fluid pulls water into this space, increasing the hydrostatic pressure locally. Because the tight junction between enterocytes is more impermeable to fluid flux than the capillary membranes, fluid and electrolytes are preferentially driven in the direction of the vascular space. Tight junctions are selective and dynamic in function and are regulated by a number of signaling pathways and cellular processes that can determine the size, selectivity, and flow of molecules across this barrier.[33,36]

The gut responds to both systemic and local stimuli to regulate motility, transport, and digestive functions. Secretion and motility are mediated through typical agonist membrane receptor mechanisms, by local autocrine and paracrine action, or through remote endocrine and neurocrine actions.[37] Regulation of intestinal motility is crucial for keeping the chyme in contact with the epithelial surface long enough for efficient absorption of nutrients while permitting removal of unusable material and bacteria from the alimentary tract on a regular basis. GI smooth muscle demonstrates phasic and tonic patterns of contraction. Numerous factors affecting the frequency of contractions include changes in autonomic tone, stimulation of the gut by neurohormonal peptides or pharmacologic agents, and noxious stimuli associated with infectious or inflammatory processes. Hypoxia and ischemia decrease motility, frequently leading to paralytic ileus. Neural regulation of the GI tract integrates the processes of intestinal water and electrolyte transport, motility, and blood flow. The augmentation of water and electrolyte absorption after a meal in the jejunum is neurally mediated.[38] The enteric nervous system is capable of functioning independently but also may be modified by the autonomic nervous system.[37,39]

Many other factors alter the functions of the gut. The terminal ileum and colon are particularly important in this respect. The presence of an ileostomy increases the risk of excessive sodium losses, dehydration, and electrolyte abnormalities. Terminal ileal resection or other diseases of the terminal ileum such as Crohn disease or radiation enteritis may result in bile acid malabsorption. In patients with bile acid malabsorption, bile acids reach the colon, which stimulates electrolyte and chloride secretion. Patients with mild to moderate malabsorption present with watery diarrhea and may respond to a bile acid binder such as cholestyramine.[40] Impairment of water and ion absorption in inflammatory bowel disease may occur due to numerous mechanisms including alteration of epithelial integrity, augmented secretion, and reduced absorption. Intestinal inflammation is associated with defects in epithelial barrier function and has a major impact on fluid and electrolyte flux.[41] Hyperosmolality of the ileal and colonic contents and the presence of unresorbed bile acids in the colon lead to a diarrheal state. This state is seen when unabsorbed nutrients enter the distal alimentary tract and are broken down by enteric bacteria, resulting in increased luminal osmotic activity and osmotic diarrhea.

Electrolyte Transport[33-35]

Several basic mechanisms exist for the transport of electrolytes by the epithelia, as summarized in Table 96.2. The presence of glucose in the lumen of the small intestine stimulates increased sodium absorption through coupled transport. Backflow of sodium into the lumen is a passive process, as a major task for the GI

tract is sodium conservation. Systemic acidosis increases Na^+ and Cl^- absorption in the ileum and colon, whereas alkalosis has the opposite effect. As seen in other epithelial tissues, aldosterone increases ileal and colonic absorption of Na^+ and can increase absorption of water in colon three- to fourfold.[42] Spironolactone blocks this effect. Glutamine has been shown to stimulate water and electrolyte absorption in the jejunum[43]; however, its overall value in intestinal rehabilitation remains uncertain. Glucocorticoids increase sodium and water absorption in the distal colon. Opiate receptor stimulation increases active sodium and chloride absorption in the ileum, and opiate antagonists decrease basal absorption of water and electrolytes. The primary antidiarrheal effect of opiates, however, is mediated through a slowing of transit time.[44,45]

In the colon, active absorption and secretion of K^+ occur in a manner consistent with K^+-H^+ exchange and are electroneutral and independent of Na^+-Cl^- exchange. The process of sodium extrusion depends on the Na^+-K^+ ATPase pumping function located at the basolateral membranes. Oxidative stress inhibits water and electrolyte absorption in the jejunum through inhibition of Na-K-ATPase on the basolateral membrane.[46]

The extrusion of Cl^- follows an electrochemical potential difference. The intraluminal secretion of water and other electrolytes appears to follow active secretion of Cl^- from the crypt cells of the jejunum, ileum, and colon with the cystic fibrosis transmembrane conductance regulator (CFTR) mechanism playing an important role.[33-35] This is a common physiologic pattern in the liver, pancreas, and kidney. Numerous substances, such as muscarinic receptor agonists, serotonin, and substance P, work through second messengers and signaling cascades to induce active chloride secretion. Vasoactive intestinal peptide (VIP) mediates increased secretion of electrolytes and water by increased cyclic adenosine monophosphate production that stimulates active chloride secretion and inhibits sodium-chloride absorption. Certain arachidonic acid metabolites, such as prostaglandins (eg, prostaglandin E_1), have been shown to increase active chloride secretion leading to increased loss of electrolytes and fluid. Many laxatives and antacids may affect fluid and electrolyte balance by stimulating active electrolyte and fluid secretion in the terminal ileum. In addition, these agents may increase mucosal permeability and stimulate motility.

Disruption of normal Na^+-K^+ ATPase activity results in the net secretion of fluid and electrolytes. This mechanism is the final common pathway in a number of secretory diarrheal states such as ischemia-reperfusion, cholera, enterotoxigenic *E.coli, Salmonella, Campylobacter jejuni,* and *Clostridium perfringens,* which appear to act via second messenger pathways via their toxins.[47] Rotavirus appears to have several mechanisms of causing diarrhea. The first appears to be a mechanism of increasing chloride secretion with a resulting secretory diarrhea mediated by Ca^{++}, a different mechanism than most bacterial mediated diarrheal diseases. The second is an osmotic diarrhea caused by villus destruction and resultant malabsorption.[48] In addition, the effects of various paracrine and endocrine mediators alter intestinal adenyl cyclase activity and lead to changes in electrolyte and water balance.

Zinc[49,50]

Zinc bears special comment because of its pluripotent effects throughout the body.

Intact zinc metabolism is required for a wide range of cellular responses including immune competence, adequate antioxidant capacity, glucose homeostasis, and wound healing. Zinc is a required cofactor for many enzymes, transcription factors, and replication factors. In noncritically ill patients, zinc supplementation may be associated with an improvement in markers of immune function. Plasma zinc concentrations are low in critically ill children, correlate with measures of inflammation, and are associated with the degree of organ failure.[51] Large intestinal losses of zinc with and without complexed proteins often occur in association with high intestinal fluid losses through stomas and fistulae. Some patients with sepsis have demonstrated significantly faster recovery with zinc supplementation among other antioxidants.[52] Thus, most PICUs tend to supplement zinc during critical illness based on experiences with adults and the burn population.[53-55]

Gastric Acid

Hydrochloric acid secretion by the gastric parietal cell is necessary for pepsinogen activation (pH <5) and to reduce bacterial colonization. H+ and bicarbonate are produced from water and carbon dioxide by the action of carbonic anhydrase within the parietal cell. The bicarbonate is secreted into the bloodstream in exchange for chloride at the basolateral membrane. Chloride and potassium are both secreted along with H+ across the apical membrane against a large concentration gradient. This is an active process, mainly due to the action of the proton pump, H^+/K^+ ATPase, which is the final step in gastric acid secretion and the site of action of proton pump inhibitor antacids (PPIs).

Histamine, gastrin, and acetylcholine are the main stimulants of gastric acid secretion. Gastric distention, dietary amino acids, and amines stimulate gastrin hormone secretion by G cells located in the gastric antrum. Gastrin is the most potent endogenous stimulant of gastric acid secretion and stimulates the release of histamine by the enterochromaffin-like cells. Histamine then binds to histamine-2 (H_2) receptors on parietal cells leading to acid secretion. Prostaglandins and somatostatin have an inhibitory effect on gastric acid secretion via specific receptors located on the parietal cell.[56]

H_2 receptor antagonists (H2RA) block histamine-mediated gastric acid secretion found in postprandial acid secretion, Zollinger Ellison syndrome, and other disorders associated with hypergastrinemia. PPIs block gastric acid secretion by inhibiting the parietal cell H^+/K^+ ATPase. They bind irreversibly to the enzyme, and subsequent secretion of acid can occur only with the synthesis of new proton pump enzyme, a process that takes 12 to 24 hours. For these reasons, PPIs have revolutionized gastric acid suppression therapy. H2RAs and PPIs are similarly effective in many patients for preventing bleeding in the upper part of the gastrointestinal tract in patients receiving mechanical ventilation.[57] Studies have shown that some oral PPIs suppress acid in ICU patients to a greater extent than intravenous preparations.[58] ICU patients at risk of stress ulcer-related bleeding are most likely to benefit from prophylaxis,[59] although the increased presence of gram-negative organisms in the upper GI tract due to antacid therapies has been implicated in ventilator-associated pneumonias.[60,61]

Pancreas

The pancreas has both endocrine and exocrine functions. The pancreas acts in concert with the liver to regulate blood glucose levels. Endocrine-secreting cells of the pancreas are aggregated in the islets of Langerhans. There are approximately 1 million islets in the human pancreas. Four distinct cell types in the islets, which serve the endocrine function, include B cells, which secrete insulin (50%-80%); A cells, which secrete glucagon (5%-20%); D cells, which secrete somatostatin (5%); and PP cells, which secrete pancreatic polypeptide.[62,63]

Branches of the celiac, superior mesenteric, and splenic arteries supply the pancreas. Venous drainage is via the pancreaticoduodenal veins, the splenic veins, and ultimately the portal vein, providing direct hormonal influence over hepatic metabolism. Both parasympathetic and sympathetic innervation of the pancreas occurs by means of the vagal nerve and abdominal plexuses, respectively. The vagal innervation of acini, islets, and ducts facilitates secretory function, whereas sympathetic innervation occurs primarily to vascular structures. Functional ectopic pancreatic tissue may be found commonly throughout the upper gastrointestinal tract.

Pancreatic Exocrine Secretory Function

The functional unit of the exocrine pancreas is the acinus composed of specialized cells containing secretory granules that drain into ductules leading to the pancreatic duct. In contrast to the pancreatic endocrine cells that demonstrate specialized function, each acinar cell is capable of secreting all the pancreatic digestive enzymes. The basolateral membrane has receptors for hormones and neurotransmitters that stimulate pancreatic secretion of the digestive enzymes stored in zymogen granules near the apical membrane of each acinar cell.[64] Ultimately, the pancreatic duct joins with the common bile duct and drains into the duodenum through the ampulla of Vater. Anatomic variation exists. Although 74% of people have a common channel, 19% have a separate opening and 7% have an interposed septum.[65]

Pancreatic juice is an isotonic fluid, containing primarily Na^+, K^+, Cl^-, and HCO_3^-. The total volume of secretion is 2.5 L daily. CFTR is the main channel for chloride secretion in the pancreas and may be involved in other ion transport.[66] Secretion of bicarbonate and water is mediated through the actions of the gut hormones secretin, cholecystokinin, and vasoactive intestinal peptide. Stimulation of the vagus nerves or the administration of acetylcholine induces digestive enzyme secretion. These effects may be blocked with atropine.

There are four phases of pancreatic secretion. *Basal secretion* represents approximately 2% of the potential maximum HCO_3^-. The *cephalic phase* is mediated by the vagal nerves in response to the sight and smell of food. The *gastric phase* consisting of secretion of a protein-rich pancreatic juice of low volume and HCO_3^- occurs following either distention of the stomach or after the ingestion of food. The *intestinal phase* is characterized by marked output of digestive enzymes, fluid, and HCO_3^-.[67,68]

The presence of bicarbonate is essential to achieve an optimal pH (pH >5) for pancreatic digestive enzyme activity and to ensure solubility of bile salts. In addition to bicarbonate, the primary secretory products of the exocrine pancreas are amylase,

lipase, and the proteases. The secondary digestive enzymes consist of nucleases, colipase, and lecithinase. The roles of the pancreatic digestive enzymes are discussed in the sections on carbohydrate digestion (amylase), lipid digestion (lipase), and protein digestion (proteases). Cholecystokinin (CCK) is the major humoral mediator of meal-stimulated enzyme secretion. It is released from the small intestinal mucosa in response to presence of fat, protein, and starch. The response is related to total load rather than concentration. CCK activates afferent neurons in duodenal mucosa, which leads to secretin release via a vasovagal reflex.[69] Inhibitors of exocrine pancreatic secretion include somatostatin, pancreatic polypeptide, and peptide YY.[67,70] Octreotide, a somatostatin analog, has been used for its antisecretory effect in clinical management of pancreatic pseudocysts and fistulae, but its use in acute or chronic pancreatitis remains controversial. It is widely used for chylous effusions and upper GI bleeding. Inflammation of the pancreas (acute pancreatitis), from both infectious and noninfectious causes, can produce a dramatic systemic inflammatory response resulting in generalized permeability changes and acute lung injury.[71]

Hepatobiliary System

Physical Examination

A complete physical examination of all children admitted to a PICU should include inspection, palpation, and auscultation of the abdomen with particular attention to hepatic or splenic enlargement, distended superficial veins, abdominal masses, the characteristics of the bowel sounds, and finally visual inspection of the perianal region for signs of trauma, fistulae, and venous distention (see also Chapters 97 and 100).

Palpation of the liver provides information about the hepatobiliary tract as well as function of the right side of the heart. Normally, the liver is palpable roughly 1 to 3 cm below the right costal margin in the midclavicular line; however, assessment of liver *span,* and not palpation alone, is the only reliable nonradiologic method for determining liver size. Liver span is determined by percussion, palpation, and auscultation along the right midclavicular line with the patient supine and breathing quietly. The dullness of the upper border is determined by percussion. Either palpation or auscultation is used to establish the lower border. The liver span increases with body weight and age in both sexes, ranging from 4.5 to 5 cm at 1 wk of age to 7 to 8 cm in boys and 6 to 6.5 cm in girls by 12 years of age.[72]

Examination of the liver should note consistency, contour, tenderness, the presence of any masses or bruits, and assessment of spleen size. Documentation of the presence of ascites and stigmata of chronic liver disease is important. Tenderness over the liver suggests inflammation or stretching of the fibrous capsule through rapid enlargement. Conditions associated with downward displacement of a normal liver include hyperinflated lungs, pneumothorax, retroperitoneal masses, and subdiaphragmatic abscess. End-stage liver disease and cirrhosis are associated with a reduced liver span corresponding to decreased hepatic cell mass. The spleen tip may be palpable normally in children, especially during inspiration. Enlargement of the spleen generally represents elevated portal venous pressures or invasive processes such as sequestration, malignancy, extramedullary hematopoiesis, or hyperplasia of the reticuloendothelial system.[73]

Anatomy: Microanatomy, Structure, and Function

The liver is the largest organ in the body and is composed of 60% hepatocytes, approximately 17% to 20% endothelial cells and Kupffer cells (reticuloendothelial cells), 3% to 5% bile ducts, and 1% hepatic stellate cells (HSCs) and oval cells. The liver has a dual vascular supply derived from the hepatic artery branches of the celiac axis providing about 30% of the blood supply and the portal vein providing approximately 70%. Innervation of the liver is by the parasympathetic branches derived from both vagal nerves and sympathetic branches, which also carry afferent fibers deriving from thoracic segments. Denervation of the liver, such as seen after liver transplantation, does not affect function.[74]

The *liver lobule*, the functional unit of the liver, is composed of interconnected hepatocytes (hepatic plates) 1 to 2 cells thick and 20 to 25 cells in length separated by a venous sinusoidal space and radiating around the central vein-like spokes in wheel (Fig. 96.1). The narrow tissue space between the endothelial cells and hepatic plates, the space of Disse, connects with lymphatic vessels in the interlobular septa. Hepatic sinusoidal endothelial cells are flat cells that do not form intracellular junctions and overlap one another. They are fenestrated, allowing plasma to enter into the space of Disse and come into direct contact with the surface of hepatocytes.[36] This facilitates bidirectional exchange between the hepatocytes and the sinusoidal space. Macrophage-derived Kupffer cells line the sinusoidal space. These cells have a phagocytic function and contribute to the hepatic inflammatory response.

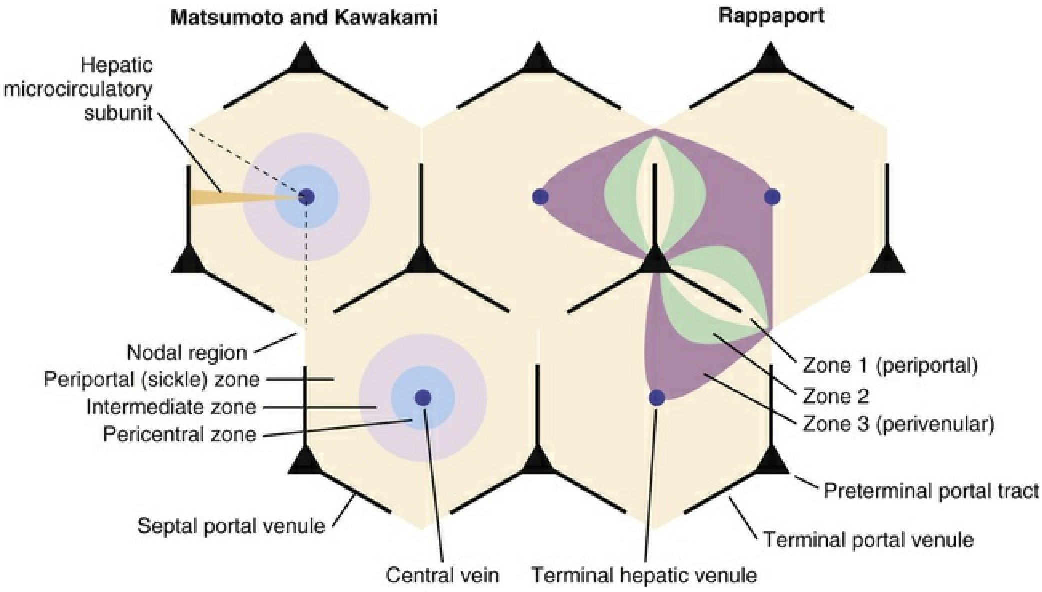

FIG. 96.1 Microanatomy of the liver depicting the hepatic acinus and microcirculatory subunits. (From Young B, et al. Wheater's Functional Hisotology: A Text and Colour Atlas. Philadelphia: Elsevier Livingstone; 2014:281.)

HSCs, also known as *ito* cells, lie within the space of Disse. HSCs serve as the hepatic storage site of vitamin A, are effectors of fibrogenesis, and play a role in extracellular matrix remodeling after recovery from injury. Chronic activation and proliferation of HSCs may lead to noncirrhotic portal hypertension, fibrosis, and cirrhosis.[75] Bile canaliculi lie between adjacent hepatocytes and drain into small

terminal bile ducts, which successively drain into larger bile ductules, intralobular bile ducts, and eventually the extrahepatic bile ducts. Tight junctions between the hepatocytes at the canalicular space permit unidirectional transport of substances from the hepatocytes into the canalicular space. Several different carriers, receptors, and transport proteins facilitate movement of compounds across the sinusoidal, hepatocyte, and canalicular membranes. ATP-binding cassette (ABC) proteins are expressed in the canalicular membrane and play an important role in transportation of organic ions.[76] Alkaline phosphatase, leucine aminopeptidase, and γ-glutamyl transpeptidase are transaminase enzymes selectively localized in the bile canaliculi and are released with injury to cells as markers of biliary disease.

The microcirculatory "path" within the lobules leads along a declining hydrostatic pressure gradient from the terminal hepatic arterioles and portal venules within the portal triad toward the central vein representing the beginning of the hepatic vein, resulting conceptually in three hepatocyte functional zones (see Fig. 96.1). Zone 1 hepatocytes closest to the portal triad are exposed to sinusoidal blood containing the highest concentration of solutes (nutrients, pancreatic hormones) and oxygen. In contrast, zones 2 and 3 represent hepatocytes more distant from the portal blood supply and are exposed to a declining oxygen and solute gradient. In addition, zone 3 hepatocytes actively participate in drug metabolism and disposition. Ischemic injury and drug hepatotoxicity impact zone 3 hepatocytes to the greatest degree.[77] Following irreversible injury in zone 3, fibrosis occurs in a pattern bridging the terminal hepatic venules leading to the stellate pattern of bridging fibrosis seen histologically.

Portal Circulation

The portal venous system drains the intestines, pancreas, and spleen with numerous collateral anastomoses to other venous beds of the abdomen. There is a mixing of portal and systemic blood circulation within the sinusoids, and all the blood eventually drains from the liver via the hepatic veins to the inferior vena cava. The liver has a high blood flow (~27% of the resting cardiac output) and low vascular resistance. The portal pressure gradient (PPG) is the pressure difference between the inferior vena cava and the portal vein. The average PPG is 0 to 5 mm Hg. Portal hypertension is defined as a PPG of between 6 and 10 mm Hg. A PPG >10 mm Hg carries risk for the development of esophageal varices, and a PPG >12 mm Hg predisposes toward ascites formation.[77,78] Obstruction of the portal venous drainage at any level leads to portal hypertension. Portal hypertension may be classified as prehepatic, intrahepatic, or posthepatic, according to the level at which the obstruction to flow occurs. The determination of the location of obstruction is critical for instituting appropriate therapy.

Ascites formation is multifactorial. The central event in ascites formation in cirrhosis is splanchnic arterial vasodilatation secondary to portal hypertension. This creates an increase in capillary pressure due to increased blood inflow leading to leakage of fluids based on classic Starling forces. Additionally, impairment of systemic hemodynamics and renal function leads to sodium and water retention with intravascular volume expansion.[79-81] Ascites may form in the absence of portal hypertension as the result of low plasma oncotic pressure associated with malnutrition, with renal or enteral protein losses, or through impaired thoracic duct

lymph drainage. Rarely, arterial-portal venous malformations may lead to portal hypertension as a result of excess portal blood flow and must be investigated when other causes of ascites are not found. One additional factor predisposing to ascites is an elevated central venous pressure that increases formation and impairs resorption of interstitial fluid often associated with generalized anasarca or other signs of right heart failure.

Hepatic Function

The function of the liver may be broadly characterized in terms of (1) production of substances uniquely made in the liver; (2) the degradation, elimination, and detoxification of biological materials; (3) the maintenance of biochemical homeostasis; and(4) storage of nutritional materials.

Substances Produced in the Liver With Pediatric Intensive Care Unit Relevance

The liver occupies an ideal place in the scheme of digestion. Hepatocytes are exposed to large quantities of absorbed nutrients after ingestion of a meal, with 20% of the total absorbed nitrogen used for hepatic protein synthesis. Of the large number of plasma proteins synthesized by the liver, several are of major significance in the PICU.

Albumin has a half-life of 18 to 20 days and is a significant contributor to colloid oncotic pressure.[82] It is synthesized solely in the liver, and decreased serum levels may predispose to edema formation and decreased binding of bilirubin, calcium, xenobiotics, and other highly protein-bound molecules. Low serum albumin levels can be secondary to impaired synthesis from protein-calorie malnutrition, chronic liver disease, cachexia, or cytokines. Alternatively, increased losses from proteinuria, protein-losing enteropathy, burns, or other iatrogenic losses including paracentesis or chest tube losses may cause hypoalbuminemia and hypogammaglobulinemia.

Prealbumin, also known as transthyretin, is a visceral protein with a short half-life of ~1.9 days. Because hepatic synthesis is exquisitely sensitive to both the adequacy and levels of protein and energy intakes, it may be used as a nutritional marker and for monitoring short-term response to nutritional intervention.[83]

α_1-Antitrypsin is an important antiprotease with regulatory activity for elastase and other plasma proteases. α_1-Antitrypsin is important in regulating elastase-induced tissue injury in certain lung diseases, and its absence leads to uncontrolled proteolytic activity in the lung.[84] Because α_1-antitrypsin is an endogenous protein that is relatively resistant to hydrolysis by enteric bacteria, it is a useful marker of protein-losing enteropathy.[85]

Hepatic synthesis of transferrin facilitates iron transport in the plasma by binding two molecules of iron. Ferritin is the primary storage molecule of iron with each molecule storing up to 4500 atoms of iron. Many coagulation factors are synthesized in the liver. They include plasminogen, fibrinogen, and factors II, V, VII, IX, X, XI, XII, and XIII. Factors II, VII, IX, and X are the so-called vitamin K–dependent factors that require vitamin K for synthesis and secretion in active form.[86] In addition, the anticlotting proteins antithrombin III, protein C, and protein S are synthesized

largely in the liver and may be vitamin K dependent (see also Chapter 91). Several additional common plasma proteins are synthesized by the liver, including haptoglobin, ceruloplasmin, lipoproteins, α-fetoprotein, and the C3 component of complement.

Alterations in plasma proteins frequently occur during acute and chronic liver disease. Although the levels of many of these proteins may rise (acute-phase reactants) as part of the systemic inflammatory response (SIRS), plasma levels are generally reduced during liver disease, depending on the duration of hepatic insufficiency and the half-lives of the specific proteins. Thus a decrease in albumin generally represents a chronic disease state, whereas a prolonged prothrombin time may be seen within hours of acute hepatic failure because of the short half-life of factor VII (~6 hours).[87]

Degradation and Elimination by the Liver

Detoxification and catabolism of ammonia, bilirubin, and xenobiotics are essential to life. Ammonia arises through bacterial degradation of nitrogenous compounds in the intestine, as well as from other physiologic sources including the kidneys and peripheral tissues such as skeletal muscle and the brain. Ammonia is transported to the liver via the portal vein in high concentrations. Ammonia is quickly metabolized in the liver to urea. High levels of ammonia are incompatible with life, and during hepatic failure, hyperammonemia represents a life-threatening aspect of liver disease.[88]

Bilirubin is derived mainly from hemoglobin degradation, and its elimination is a critical excretory function of the liver. Smaller amounts are made through the breakdown of cytochromes and myoglobin. Heme is broken down into bilirubin in the reticuloendothelial system. Hepatic metabolism of bilirubin involves several steps, including transport to the hepatocyte and cellular uptake, cytosolic transport within the hepatocyte, conjugation, active cellular export, and elimination. Impairment at any step becomes manifest as hyperbilirubinemia and ultimately clinical jaundice. It may be defined as prehepatic if production is increased beyond the ability to clear or cholestatic if the conjugated bilirubin cannot not be excreted.

Enterohepatic Circulation

Bile acids represent a family of steroid molecules derived from cholesterol. They eliminate cholesterol from the body and solubilize dietary fats through a detergent-like action. Enterohepatic circulation conserves bile acids because a minimum concentration of bile acids is required for micelle formation. Bile salts are secreted into the duodenum with 97% reuptake in the terminal ileum, undergoing recycling 4 to 12 times per day. The distal and terminal ileum have specialized transport mechanisms for absorption of bile salts and vitamin B_{12}, which are adversely affected by terminal ileal resection, jejunostomies, inflammatory bowel disease, or other acquired lesions in this anatomic region (eg, necrotizing enterocolitis). Functional loss of the distal and terminal ileum results in malabsorption of vitamin B_{12}, bile salt deficiency, and impaired digestion and absorption of fat-soluble vitamins and long-chain fats. Furthermore, unresorbed bile acids entering the colon play a major role in secretory diarrhea.

Hepatic insufficiency, either from immaturity or as a result of disease, affects the elimination of many drugs. A large number of commonly used drugs of all classes including aminophylline preparations, narcotics, barbiturates, H_2-blockers, vasodilators, antidysrhythmics, and others demonstrate significant hepatic elimination. The hepatic P-450 (CYP) system plays a central role in many of the mixed-function oxidative reactions responsible for converting lipophilic compounds into more water-soluble ones.[89,90] The liver may conjugate drug metabolites to form hydrophilic products that can be eliminated easier in bile or through the kidney. The half-life of many drugs may be prolonged during hepatic insufficiency as a result of a decrease in the total number of functioning hepatocytes. In addition, the half-life of many drugs may be prolonged through competitive inhibition by the presence of other drugs, or it may be shortened by the induction of rate-limiting elimination pathways. For example, phenobarbital decreases the half-life of xanthines and may increase the toxicity of acetaminophen. Adjustment of medication dosage and schedule must be considered for those drugs with significant hepatic elimination when impaired liver function exists.[36]

Hepatic Regulatory Function

The liver provides major counterregulation through (1) interconversion of amino acids to maintain physiologic plasma levels, (2) gluconeogenesis to maintain adequate serum levels for glucose-dependent tissues, and (3) regulation of numerous plasma hormones (Box 96.4). The direct secretion of insulin and glucagon into the portal circulation exposes the liver to concentrations up to 10-fold greater than peripheral tissues. This relationship amplifies the hepatic influence over carbohydrate metabolism. Approximately 50% of secreted insulin and a large portion of glucagon are degraded on a first-pass basis by the liver. Both of these hormones are known to have hepatotrophic effects and are thought to be important for differentiation and regeneration of hepatocytes. Intensive insulin therapy in the critical care setting has been shown to have a beneficial effect on liver function.[91]

Box 96.4

Hepatic Endocrine Regulation

Catabolism Primarily by Liver

- Insulin
- Glucagon
- Growth hormone
- Glucocorticoids
- Estrogens
- Progesterone
- Parathyroid hormone

- Some gut hormones

Catabolism by Liver and Other Tissues

- Thyroid hormone
- Luteinizing hormone
- Antidiuretic hormone
- Testosterone
- Aldosterone
- Oxytocin
- Adrenocorticotropic hormone
- Thyroid-stimulating hormone
- Thyroid-releasing hormone

Storage Function

The last category of hepatic function involves storage of glycogen, triglycerides, folic acid, vitamin B_{12}, and vitamins A and D. The liver uses glycogenolysis to mobilize hepatic glycogen stores and provide an almost immediate source of glucose to maintain serum levels. The liver glycogen stores contain up to a 2-day supply of glucose,[92] although these can be depleted rapidly by infants who become ill and have a decrease in oral nutrition. Synthesis of vitamin D_3 (cholecalciferol) occurs in the skin with subsequent accumulation of D_3 in the liver. Hydroxylation in the 25-position that occurs in the liver results in a large pool of circulating 25-(OH)D_3, the precursor of the active 1, 25-(dihydroxy) D_3. Defective storage and absorption of dietary vitamin D and 25-hydroxylation may be present in chronic liver failure.[93,94]

Host-Defense Mechanisms of the Gut: Immunology and Microbiology

Both the intestine and the hepatic-based macrophages can serve as major sources of nitric oxide following injury or stimulation[95] and contribute to the gastrointestinal tract's role in systemic responses. The frequent association of hepatic dysfunction with the acute respiratory distress syndrome has led to intensive investigation of the lung-liver axis during critical illness.[96] A major unifying theme in these organ interactions is the regional activation of macrophages and platelets and damage to the endothelium after injury leading to both localized and remote organ function disturbance. The gut has become one of the important focuses in our evolving understanding of multiple organ dysfunction syndrome (MODS) (see also Chapter 112).[7]

The gastrointestinal tract is the largest immunologic organ in the body and is

where 80% of the body's entire immune system resides. [97] As such, the gut is in a constant state of controlled inflammation, serving essentially three immunologic functions: (1) to achieve tolerance to commensal microbiota and dietary proteins, (2) to induce destruction or elimination of pathogenic organisms and antigens, (3) to suppress the tendency toward dysplasia in this chronically "controlled" inflammatory environment. Although these processes develop from birth to adulthood, the gut also undergoes developmental changes in the microbiome.[98] Based on multiple studies, it is clear that the components of the microbiome have affects on health and disease of the gut immune system as well as the rest of the body.[99,100]

Immunologic Processes of Gut

When an antigen is presented to the gut, it must survive exposure to several nonimmune protective measures (referred to innate immunity) including salivary and pancreatic enzymes, low gastric pH, the detergent effect of bile acids, the "house cleaning" function of intestinal motility, and the protective effects of the mucus layer above the epithelium. Once antigen reaches the epithelium, dendritic cells "sample" the antigen, process it, and then a response occurs involving either destruction/elimination of the antigen or tolerance of the antigen. The cells of the gut-associated lymphoid tissue (GALT) involved in this highly complex and coordinated dance are roughly organized into three compartments: diffusely scattered through the lamina propria, within the epithelium itself, and into lymphoid follicles called Peyer patches. A key theme in this complexity is the understanding that these cells have developed from evolutionary archaic *innate* cell function to more advanced *adaptive* functions. They have evolved to form both innate and adaptive immune responds (Table 96.3). The cellular basis of immunity in the gut depends on the production of mucus by goblet cells, alpha-defensins by Paneth cells, and tight junctions preventing penetration by large peptides once gut "closure" occurs. IgA is produced in response to gut flora binding to bacteria and sweeping them out in the feces.

TABLE 96.3
Innate and Adaptive Immunity

Innate Immune System	Adaptive Immune System
Naively responds to invading pathogens/antigens Phylogenetically older defenses (eg, lectins, surfactants, chetlidicins, defensins) Antigen presenting cells: phagocytes, dendritic cells	Allows for memory and suppression, T- and B-cells Provides rapid response to known antigens Adapts and suppresses reaction to future exposure

(See also Chapters 101 and 102.)

Lymphocytes play a central role in the balanced inflammatory response within the intestine and recapitulate patterns of control common to specialized lymphocyte population elsewhere in the body (see also Chapter 102).[101,102] In the infant, lymphocytes in fresh breast milk can invade the GALT and confer the mother's immunologic memory to the naive infant's immune system. Similarly, intact protein can permeate the epithelium and lead to sensitization to foreign proteins as is seen in cow's milk protein sensitivity. The intestinal lymphocytes depend on vitamins A and D as well as zinc for generation of T lymphocytes, suggesting the importance of

micronutrients in intestinal immune function.

The intestinal flora or microbiota are extremely important for systemic health and are frequently disrupted by the broad-spectrum antibiotics used in critically ill patients.[99,100] For example, early studies of mice raised in a germ-free environment suggested the importance of a healthy balance of intestinal bacteria, whereas small bowel bacterial overgrowth is a well-recognized source of chronic diarrhea and morbidity in children.[103] Dysbiosis is a known factor in several common diseases seen in the PICU including *C. difficile* colitis, Crohn disease, ulcerative colitis, and necrotizing enterocolitis.

The continual crosstalk between the GALT and intestinal contents provides a critical feedback mechanism for counterregulation of the lymphocyte pools.[104] This area of intestinal immunology is under active investigation, although the importance of the intestinal flora in restoring and maintaining health is beyond question. Evidence for this effect comes from the 90% cure rate for *C. difficile* colitis achieved through fecal material transplantation.[105,106] In addition, the role of the intestinal bacteria in drug and bile salt metabolism has only become appreciated.[107]

The interaction between gut and brain has come under investigation with numerous small series studies demonstrating important effects of the intestinal microbiome with behavioral and psychologic conditions (depression, autism, etc.).[39] This observation has led to the concept of the gut-brain axis.[108,109] Its implications for the intensivist are far less clear than the data on restoring healthy gut flora but may have implications for a range of issues dealt with in the PICU including delirium, muscle wasting, and the like.

Bacterial translocation is defined as the migration of bacteria or bacterial products from the intestinal lumen to mesenteric lymph nodes or other extraintestinal organs, representing a disruption of the normal host flora equilibrium that leads to a self-perpetuating inflammatory response and ultimately to infection.[110] This process is increasingly being recognized as a potential source of pathogens producing bacteremia and sepsis in a variety of premorbid disease conditions such as cirrhosis and prematurity.[111,112] Translocation may occur directly through the M cells that cover the Peyer patches or it may occur by ingestion of viable pathogenic material by the mobile phagocytic system with transport into the host bypassing the previously outlined barrier mechanisms. Alteration in intestinal microbiome, host immune defenses, and damage to the microcirculation predispose to bacterial translocation. *E. coli, Proteus mirabilis,* and *Klebsiella pneumoniae* appear to be more commonly associated with translocation from the gastrointestinal tract.

Kupffer cells, which account for the largest pool of mononuclear phagocytes with direct access to the blood, play a major role in clearing portal bacteria. In addition, Kupffer cells are key participants in response to tissue injury or organ invasion through the elaboration of cytokine mediators, such as tumor necrosis factor (TNF) and interleukin (IL)-1, and the release of nitric oxide, leading to many of the systemic responses seen in sepsis.[95] Through their intimate proximity to the hepatocyte, Kupffer cells interact directly with hepatocytes by means of cell-cell and paracrine interactions. In response to TNF and IL-1, well-documented alterations in hepatic function occur, including the inhibition of albumin synthesis, gluconeogenesis, and P-450–mediated detoxification. Acute-phase reactant synthesis is also induced by TNF, IL-6, and IL-1.[113]

Gastrointestinal and Hepatobiliary Testing in the Intensive Care Unit

Diagnostic testing in the ICU permits the identification of organ system injury and dysfunction and assists in monitoring the course of a disease as well as its response to therapies. Laboratory testing is helpful in detecting and monitoring hepatocellular injury and dysfunction. In the ICU setting, impaired synthetic function is the hallmark of liver failure. This is of more immediate concern than hepatocellular injury alone. Decreased synthesis of the liver-dependent clotting factors I (fibrinogen), II (prothrombin), V, VII, IX, and X, results in a prolonged prothrombin time (PT). In the absence of vitamin K deficiency or related inhibitors, this represents liver failure. Because factor VII has the shortest half-life (2 to 6 hours) compared to the other factors, it acts as the rate-limiting step for conversion of prothrombin to thrombin. The use of recombinant activated factor VII in acute liver failure remains under debate.[87,114] Other less specific measures of liver dysfunction include increased bilirubin, decreased serum albumin, and decreased prealbumin.

Liver failure may also be associated with life-threatening hypoglycemia due to decreased hepatic synthesis and release of glucose, hyperinsulinemia from impaired hepatic degradation, and increased glucose utilization secondary to anaerobic metabolism. Plasma ammonia is frequently elevated resulting from urea cycle defects, portal systemic shunting, and events such as gastrointestinal bleeding that lead to increased ammonia production by enteric bacteria

Liver disease can be broadly categorized into hepatocellular, cholestatic, and infiltrative processes. The biochemical tests commonly used to detect cholestasis, which is impaired bile flow and hepatocellular injury, are serum bilirubin and aminotransferase activities (alanine transaminase [ALT], aspartate transaminase [AST]). Cholestasis, reduced bile excretion or transport, and biliary obstruction in the bile canaliculi or large ducts are represented by elevations in serum conjugated bilirubin, bile acids, alkaline phosphatase (ALK), γ-glutamyltransferase (GGT), or 5′-nucleotidase (5-NT).

The van den Bergh reaction assesses conjugated (direct fraction) bilirubin levels. The unconjugated (indirect) fraction represents the difference between the total bilirubin and the direct fraction. Elevated levels of indirect bilirubin result from (1) increased bilirubin load to the liver (eg, hemolysis), (2) diminished uptake and intracellular transport, and (3) reduced conjugation (eg, immaturity, fulminant necrosis).

In children, elevations in ALK may be seen with rickets or during periods of rapid skeletal growth. Isoenzymes of ALK may distinguish between liver or bony sources. Alanine transaminase (ALT or SGPT) and aspartate transaminase (AST or SGOT) are hepatic cytosolic enzymes that catalyze the reversible transfer of the α-amino group of the amino acids alanine and aspartic acids to the α-keto group of α-ketoglutaric acid producing pyruvic and oxaloacetic acids, respectively, plus glutamate. Elevations in serum activities of ALT and AST suggest hepatocellular injury (Table 96.4). AST is also present in myocardial tissue, skeletal muscle, kidney, pancreas, and erythrocytes; therefore increased AST is not specific for hepatocellular injury. ALT is present in only relatively low concentrations in tissues other than liver, providing greater specificity for hepatocellular injury than AST. Falling levels of AST and ALT in the setting of rising levels of conjugated bilirubin and ammonia represent

increased destruction of hepatocytes rather than recovery. Elevated serum lactate dehydrogenase activity (LDH) lacks specificity and may be seen in association with hepatocellular injury, hemolysis, and myopathy; however, when in association with elevated serum creatinine phosphokinase (CPK) or aldolase, elevated LDH indicates myopathy or a rhabdomyolysis (Table 96.5).

TABLE 96.4

Pattern of Biochemical Tests Based on Category of Liver Disease

Biochemical Test	Hepatocellular Necrosis	Cholestasis	Infiltrative Process
ALT, AST	++ to +++	0 to +	0 to +
ALK, GGT	0 to +	++ to +++	+
Total/conjugated bilirubin	0 to +++	0 to +++	0 to +
PT	Prolonged	Prolonged; responsive to vitamin K	0
Albumin	Decreased in chronic disorders	Decreased in chronic disorders	0
Cholesterol	0	0 to +++	0
Bile acids	+ to +++	+ to +++	0

0, normal; + to +++, degrees of elevation.

ALK, alkaline phosphatase; *ALT*, alanine transaminase; *AST*, aspartate transaminase; *GGT*, g-glutamyltransferase; *PT*, prothrombin time.

TABLE 96.5

Diagnosis of Selected Hepatobiliary Disorders

Form of Liver Injury	Supportive History/Laboratory Data
Predominantly Hepatocellular	
Viral hepatitis	Viral serologies: hepatitis A, B, C, E, EBV, CMV, VZV, HSV
Drug-induced hepatitis	History of toxic/excess ingestion, ± elevated Eosinophil count
Ischemia	Shock, postcardiac surgery
Autoimmune hepatitis	Increased globulin ratio, antinuclear antibody, antismooth muscle antibody, antiliver kidney microsomal antibody
Wilson disease	Serum ceruloplasmin, 24-hour urine copper
α-antitrypsin deficiency	Pi typing
Cholestatic	
Bacterial sepsis	*Proteus, E. coli,* UTI
Galactosemia	Urine-reducing substances, *E. coli,* sepsis, red blood cell galactose-1-phosphate uridyltransferase
Tyrosinemia	Urine succinylacetone
Biliary atresia	Intraoperative cholangiogram
Anatomic anomalies: choledochal cysts, biliary stricture, cholelithiasis, congential hepatic fibrosis, Caroli disease	Ultrasonography, cholangiogram
Alagille syndrome	Butterfly vertebrae, posterior embryotoxon on eye exam, echocardiogram
Cystic fibrosis	Sweat test, genetic testing
GVHD, veno-occlusive disease	History of bone marrow transplant, high-dose busulfan
Ischemia	ECLS
Infiltrative	
Hepatocellular carcinoma, hepatoblastoma	α-Fetoprotein
Predominantly Coagulopathy	
Neonatal hematochromatosis	Serum iron and ferritin

CMV, cytomegalovirus; *EBV*, Epstein Barr virus; *ECLS*, extracorporeal life support; *HSV*, herpes simplex virus; *VZV*, varicella zoster virus.

Imaging of the hepatobiliary system has become easier, safer, and more reliable. Ultrasonography is particularly useful in the ICU and allows rapid, safe, bedside evaluation of (1) hepatic vascular structures and patterns of blood flow; (2) structural abnormalities such as tumors, abscess, hematoma, or dilated intrahepatic bile ducts;

(3) the gallbladder, extrahepatic, pancreatic, and common biliary system; (4) the pancreas; (5) the genitourinary system; and (6) the abdomen and retroperitoneum (see also Chapter 20). In addition, ultrasound can provide guidance for therapeutic interventions such as drainage of abscesses.

Computed tomographic (CT) scan with and without contrast has become the diagnostic procedure of choice for evaluating the abdomen following trauma and in the ICU. Magnetic resonance imaging (MRI) provides an additional method for evaluating the abdominal and retroperitoneal organs for masses, abscesses, and fluid collections as well as vascular structures when contrast is administered.[115] A downside to both modalities is that they usually require a prolonged period away from the ICU, although rapid sequence CT and MRI procedures have reduced acquisition time for unstable patients.

Many of the radioisotope studies can be performed in the ICU when a portable scintillation camera is available. Technetium-99m (^{99m}Tc) IDA compounds are handled by the hepatobiliary system much like bilirubin and provide a qualitative and semiquantitative image of function and structure. These compounds may be used diagnostically to evaluate infants with persistent jaundice and also used in follow-up after the Kasai procedure or liver transplantation.

Of the available biochemical markers of pancreatic disease, serum amylase and lipase determinations are the most widely available. Serum lipase is elevated in about 87% of patients with acute pancreatitis and demonstrates fewer false-positive results than amylase testing. Transient hypocalcemia (<8 mg/dL) occurs in about 30% of patients with pancreatitis. Mild to moderate hyperglycemia as a result of islet cell damage is seen in up to 25% of cases, often necessitating the administration of exogenous insulin.

Evaluation of the alimentary tract consists of examining gastric aspirates and stool samples for gross bleeding or occult blood with the guaiac test (hemoccult). A positive result mandates further evaluation and surveillance to determine the source and severity of gastrointestinal tract blood loss. Nasogastric lavage may be used to distinguish a source of bleeding as being proximal or distal to the pylorus. ^{99m}Tc sulfur colloid or red blood cells labeled with ^{99m}Tc may provide information regarding the site of active mucosal bleeding and are less invasive than arteriography.

Esophageal pH monitoring is useful for evaluating the efficacy of antisecretory therapy. It may be useful to correlate symptoms (eg, cough, chest pain) with acid reflux episodes and to select those infants and children with wheezing or respiratory symptoms in whom gastroesophageal reflex (GER) is an aggravating factor. The sensitivity, specificity, and clinical utility of pH monitoring for diagnosis and management of possible extraesophageal complications of GER are not well established.[116]

Imaging studies are of primary importance in acutely ill patients in a number of circumstances. Plain radiographs can be reliably used to locate radiopaque objects and to diagnose intestinal ileus, mechanical obstruction, and perforated viscus. Contrast studies are required to diagnose organ and soft tissue inflammation including appendicitis, pancreatitis and its complications, mesenteric and retroperitoneal masses, abscesses/fluid collections, intussusceptions, and anatomic anomalies.

Gastrointestinal bleeding from sites distal to the ligament of Treitz and proximal

to the terminal ileum—sites that are inaccessible to video endoscopy, such as Meckel diverticulum, vascular malformations, and altered anatomy post gastrointestinal surgery—is best assessed using radio nuclide scans and angiography. Because of the need to perform the more sophisticated imaging studies away from the controlled environment of the ICU, the studies must be tailored to the patient's diagnostic needs according to the priorities of the initial stabilization of life-threatening illness and subsequent treatment of the underlying pathologic condition.

Video and or fiberoptic endoscopy in the hands of operators skilled in managing small children has found a place in ICU management to diagnose the source of upper gastrointestinal tract bleeding, to control and sclerose bleeding varices, to place percutaneous gastrostomy tubes for feeding, and for the placement of stents to maintain patency of the distal biliary and pancreatic tract.

CHAPTER 97

Disorders and Diseases of the Gastrointestinal Tract and Liver

Claire Stewart, Samuel A. Kocoshis

PEARLS

- So much reliance is placed on electronic monitoring of patients that physicians are often tempted to perform only a cursory examination or go days without laying hands on the patient. Regrettably, adopting such an approach deprives the clinician of an adequate perspective on the patient's day-to-day condition and deprives the patient of optimal care.
- When compared with a scintiscan of the lungs after administration of a radiolabeled meal or with the discovery of lipid-laden macrophages after bronchoalveolar lavage, the use of colorants to monitor for aspiration pneumonitis is notoriously inaccurate.
- Several antireflux barriers exist in the region of the lower esophageal sphincter. Beyond intrinsic myogenic tone, barriers such as the cardioesophageal angle, the abdominal esophagus (which acts as a flutter valve), the mucosal rosette of the sphincter (which acts as a choke valve), and the diaphragmatic crura themselves act to prevent reflux of gastric contents.
- The association between *Helicobacter pylori* infection and both chronic gastritis and duodenal ulcer is well established, but the role of *H. pylori* in the pathogenesis of gastric ulceration remains somewhat speculative.
- Intravenous administration of somatostatin or its synthetic analogue, the active octreotide moiety, has been effective in stemming variceal hemorrhage and may work for other causes of gastrointestinal bleeding. In addition to their hemodynamic effects, these agents inhibit gastric acid production.
- Crohn disease and ulcerative colitis are chronic, relapsing disorders without known causes. The transmural inflammation of Crohn disease may affect any portion of the alimentary tract in a patchy distribution, whereas the inflammation of ulcerative colitis is confined to the mucosa of the colon.
- An abdominal plain film showing pneumatosis intestinalis, hepatic portal air, or

both confirms the diagnosis of necrotizing enterocolitis. Because the pathogenesis is unknown, treatment must be symptomatic. In most centers, feedings are discontinued for 48 hours to 2 weeks depending on the severity of symptoms. Fluid resuscitation and broad-spectrum parenteral antibiotics are the bases of medical therapy. Surgical resection is reserved for severe cases when medical management fails and gangrenous bowel develops.

- Abdominal compartment hypertension and syndrome are two distinct entities becoming increasingly recognized in the intensive care setting. Prompt recognition of clinical symptoms and signs may prevent vital organ compromise.

Gastrointestinal Evaluation of the Critically Ill Child

Dramatic advances in pediatric critical care have improved outcomes for children admitted to pediatric intensive care units (PICUs). Indeed, the technology available today has improved management strategies for a variety of conditions. So much reliance is placed on electronic monitoring of patients that physicians are often tempted to perform only a cursory examination or go days without laying hands on the patient. Regrettably, adopting such an approach deprives the clinician of an adequate perspective on the patient's day-to-day condition and deprives the patient of optimal care. Daily physical examination is of paramount importance in the assessment of children with either life-threatening gastrointestinal disease or gastrointestinal manifestations of multisystem disease. This chapter therefore reviews the current approach to gastroenterologic diagnosis and therapy as well as the principles of gastroenterologic physical examination.

Abdominal Examination

Astute clinicians recognize that the abdomen extends from the neck to the knees. A thorough examination of the head, neck, and chest is essential when patients with abdominal symptoms are evaluated. For example, pneumonia may be discovered by chest auscultation in the child who has abdominal pain.

The abdominal examination, which can be difficult to perform on young children without life-threatening illness, is made more difficult in the ICU setting. Pain and fear limit cooperation. Patients who are obtunded by narcotics, sedatives, or an underlying central nervous system (CNS) disorder display inconsistent responses to abdominal palpation. Neuromuscular blockade abolishes abdominal guarding. Children with multisystem trauma may not localize pain. These impediments notwithstanding, the observant clinician can glean a great deal of information from a carefully performed examination. Simple inspection of the child's abdomen can reveal generalized distention, abnormally prominent abdominal wall veins (which signify portal hypertension), or anterior and lateral abdominal wall ecchymoses, such as Cullen sign or Grey Turner sign (which herald acute pancreatitis). In addition, because of the child's relatively undeveloped abdominal musculature, visceromegaly or abdominal masses may be apparent on inspection.

Auscultation will ascertain the frequency and quality of peristaltic sounds. They normally occur every 10 to 30 seconds and are low pitched. High-pitched, frequent bowel sounds suggest enteritis or obstruction. In obstruction, bowel sounds characteristically reverberate and seem to originate from a deep well. Bowel sounds are absent in paralytic ileus or peritonitis. Ancillary findings include venous hums, which suggest portal obstruction, or bruits that may denote arteriovenous malformations.

In pediatric patients, palpation should generally precede percussion because it is less threatening. The child should be in the supine position, and when possible the hips and knees should be comfortably flexed to enhance abdominal wall relaxation. The abdomen should be palpated through all phases of respiration in all four quadrants. The examiner should lightly palpate to judge guarding and tenderness and should use gentle ballottement. Deeper palpation better localizes organomegaly or masses.

Percussion permits estimation of visceral size and helps to diagnose obstruction, peritonitis, or ascites. Excessive tympany implies that bowel loops are distended with air, whereas dullness suggests that excessive fluid or a solid mass is present. Shifting dullness is relatively easy to detect in cooperative children with percussion of the abdomen with the child in the supine, left lateral, and right lateral positions. When the child with ascites is in the supine position, dullness is found primarily over the flanks. The dullness moves to a new level nearer the midline when the child is moved to each lateral position. It is essential to perform a digital examination of the rectum in children with gastrointestinal dysfunction. Inspection of the perineum may reveal perianal or perirectal abscesses, which may be the first sign of acute leukemia, chronic granulomatous disease of childhood, or Crohn disease. Similarly, deep fissures or sentinel piles suggest ulcerative colitis or Crohn disease, and hemorrhoids can be found in portal hypertension. The digital examination should be performed in the alert, older child only after its purpose is explained. Any material that returns on the examining finger should be evaluated for occult blood. Absence of stool in the vault can corroborate Hirschsprung disease in an infant with abdominal distention and a history of obstipation. Rectal masses related to pelvic abscesses or tumors may be digitally palpated. Rectal tenderness signifies mural or extramural inflammation or infection.

Gastrointestinal Endoscopy

The development of flexible fiberoptic endoscopes appropriately sized for use in infants and children has greatly expanded the value of endoscopy in diagnosing and treating a variety of gastroenterologic disorders in critically ill pediatric patients. For example, pediatric endoscopes with an outside diameter of 5 mm can now be used for diagnostic purposes in newborn infants. Electrocautery, injection therapy, or variceal banding of gastrointestinal bleeding sites can also be performed with devices that now fit within the biopsy channels of a standard 9.4-mm pediatric endoscope. Upper gastrointestinal endoscopy (esophagogastroduodenoscopy [EGD]) is performed most often with the child under deep sedation or general anesthesia, although some clinicians report successful unsedated upper endoscopy in very young infants. Many pediatric endoscopists in North America use a combination of narcotic sedative and benzodiazepine to achieve acceptable sedation

analgesia.[1] Other agents commonly used for sedation are propofol and ketamine. General anesthesia with endotracheal intubation is appropriate when the side effects of sedation or the endoscopy pose an undue risk of respiratory compromise (eg, when underlying pulmonary disease, upper airway disease, or disorders of respiratory control are present) or if the patient is at risk for aspiration of gastric contents (eg, when massive upper gastrointestinal hemorrhage is present or when an emergency foreign body extraction is performed on a child with a full stomach). In an ICU setting, patients supported by ventilators should receive additional sedation and neuromuscular blockade if the endoscopist anticipates that the procedure will be lengthy or excessively difficult.

Advantages of elective endotracheal intubation for EGD also include control of both the airway and ventilation during the procedure. In very small patients, the relatively large endoscope may partially obstruct the glottis. Distention of the gut with air may interfere with diaphragmatic movement. The risk of inadvertent extubation during EGD, however, mandates careful fixation of the endotracheal tube and careful monitoring of ventilation during the procedure by a physician from the critical care team.

Because bacteremia may occur during both upper and lower gastrointestinal endoscopy, some endoscopists routinely use perioperative antibiotics for endoscopy in patients with a central venous line or ventriculoperitoneal shunt. Therapeutic endoscopy has complemented diagnostic endoscopy. Gastrointestinal tract hemorrhage from varices, peptic ulceration, and angiodysplasia may be controlled by injection therapy or photocoagulation, electrocoagulation, and thermocoagulation. Band ligation of esophageal varices is also a proved therapy for variceal hemorrhage. Percutaneous endoscopic gastrostomy has become a popular alternative to surgical gastrostomy to provide a reliable route for enteral nutrition for patients in the ICU who cannot take oral alimentation on a long-term basis.

The diagnosis and treatment of oropharyngeal dysphagia can be difficult but are improved with the use of fiberoptic endoscopic evaluation of swallowing (FEES). The endoscope can be passed transnasally to visualize both laryngeal and pharyngeal structures. Both the structure and functioning of the pharyngeal phase of swallowing can be evaluated by giving the patients food and liquid boluses. Sensory testing can also be conducted to elicit the laryngeal adductor reflex. Some studies have suggested a good correlation between FEES and videofluoroscopy.

Wireless video endoscopy or video capsule endoscopy (VCE) is a noninvasive technology used to provide imaging of the small intestine, an anatomic site often difficult to visualize. The images acquired are of excellent resolution and the procedure uses the principle of physiologic endoscopy via passive movement and does not inflate the bowel, so images of the mucosa are captured in a collapsed state. Primary indications include the diagnosis of obscure gastrointestinal bleeding, small bowel tumors, or Crohn disease. There is growing experience in the use of this technology for children older than 6 years. Advantages include its noninvasive nature and the ability to examine the small bowel mucosa, which is not possible with push enteroscopy. Disadvantages include the impossibility of any tissue sampling or therapeutic intervention. However, studies have suggested that the overall yield of VCE is superior to push enteroscopy and barium studies.[2-4]

Gastroesophageal Reflux Monitoring

Like gastrointestinal endoscopy, esophageal reflux monitoring has benefited from technical advances that permit insertion of miniature, flexible electrodes into the esophagus of the smallest children. Esophageal impedance monitoring[5-7] has become the preferred means of measuring gastroesophageal reflux in children, especially among patients who are receiving acid suppression or in whom weakly acidic or alkaline reflux is suspected, as impedance monitoring is independent of pH. The intraesophageal impedance device measures total opposition to current flow between two electrodes and expresses the value in ohms. Because air and fluid have different conductivities, the contents of the esophagus can be differentiated at any point in time. Thus when the esophagus is devoid of fluid, baseline impedance is measured. When a bolus of fluid enters the esophagus from refluxed material or from a swallowed bolus, the impedance changes. These changes in intraluminal impedance thus permit the continuous monitoring of pH neutral or alkaline reflux episodes.

In addition to detecting pathologic quantities of reflux in children who have symptoms suggestive of reflux disease, reflux monitoring is also useful in determining whether a temporal correlation exists between gastroesophageal reflux and pathologic events such as cough, bronchospasm, or apnea. Because it does not determine the cause of vomiting, reflux monitoring adds little to the evaluation of vomiting children.

Use of Colorants to Identify Aspiration in the Intensive Care Unit

Patients who are obtunded or who have been ventilator dependent for an extended time are at significant risk of pulmonary aspiration. A deceptively simple way of documenting aspiration in patients receiving gavage or gastrostomy feedings in the past has been to add a coloring agent such as blue dye No. 1 or methylene blue to the formula. The rationale for this strategy was that quantities sufficient to tint formula should be readily apparent when suctioned from the lungs. The fallacy of the technique is that when compared with scintiscanning of the lungs after administration of a radiolabeled meal or with the discovery of lipid-laden macrophages after bronchoalveolar lavage, the use of colorants is notoriously inaccurate. Furthermore, all colorants are dangerous when instilled into the gastrointestinal tract. They are customarily absorbed in minimal quantities, but among critically ill patients, the gastrointestinal tract becomes porous to all macromolecules and appreciable quantities of dye are absorbed. Once absorbed, even minimal quantities function as metabolic poisons, uncoupling oxidative metabolism, thereby resulting in life-threatening metabolic acidosis among susceptible patients.[8]

Radiologic Procedures

Plain Films

The abdominal x-ray film provides valuable assistance to the clinician evaluating children with abdominal distention, guarding, or tenderness. Dilated, gas-filled

bowel loops, with or without air-fluid levels, can signify obstruction or ileus. Air-fluid levels in a stepladder configuration along the length of small bowel suggest obstruction, whereas levels that appear in a parallel configuration suggest ileus. Pneumatosis intestinalis and mucosal thumbprinting are signs of bowel wall ischemia and can often be appreciated on the plain film. Pneumoperitoneum can be evaluated with the inspection for air in the lesser sack, air between bowel loops, or a visible falciform ligament. Even though an upright film is optimal for visualizing peritoneal air, lateral decubitus or cross-table lateral films are acceptable substitutes in bedridden patients. Air in an abscess cavity or air in liver parenchyma, biliary tree, or portal venous system should be acknowledged as signs of serious intraabdominal infection.

Abnormal densities such as abdominal masses, ascites, or calcifications can often be identified on plain films. Calcifications in the region of the gallbladder, pancreas, or appendix suggest cholelithiasis, pancreatitis, or appendicitis, respectively. The abdominal contour and the contour of extraperitoneal structures such as lung bases, pelvic organs, and kidneys should always be assessed.

Contrast Radiography

Although endoscopy is more sensitive than single-contrast radiography for identifying mucosal ulceration, contrast radiography remains a valuable procedure in the critical care setting. In general, the upper gastrointestinal tract series and small bowel series are indicated when partial small bowel obstruction is suspected. A contrast enema will document (and possibly treat) intussusception and document Hirschsprung disease. The type of contrast agent for a particular examination depends on the clinical condition of the patient undergoing the examination. Although barium sulfate is superior to water-soluble contrast agents for outlining mucosa, its use in typical ICU patients is riskier because barium may form a concretion in a patient with ileus and because barium leaking into the peritoneum from a perforated hollow viscus can cause serious peritoneal injury. Hyperosmolar, water-soluble contrast agents are usually not favored because they pose the risk of dehydration. Currently, isosmolar agents are more commonly used for studies on the critically ill patient.

Ultrasonography, Computed Tomographic Scanning, and Magnetic Resonance Scanning

Ultrasonography, computed tomographic (CT) scanning, and magnetic resonance imaging (MRI) each has advantages and disadvantages. For example, in the slim child with little mesenteric fat, ultrasonography is sometimes better than CT scanning of abdominal viscera. Conversely, CT scanning is superior for abdominal imaging of obese individuals.[9] MRI is limited by its inability to distinguish bowel loops from adjacent structures and by blurring caused by motion. It is helpful, though, in identifying vascular tumors, which are seen as low-intensity masses on T1-weighted images and high-intensity masses on T2-weighted images. Ultrasonography or CT is used when an intraabdominal abscess, cystic lesion, hepatobiliary disease, tumor, ascites, or pancreatitis is suspected. In the identification of pancreatic lesions, dynamic CT scanning is the preferred imaging technique. CT also best identifies enlarged periaortic lymph nodes. CT and magnetic

resonance enterography are other modalities used to detect small bowel inflammatory disease. Oral hyperhydration can achieve adequate luminal distention, often not requiring nasoenteric intubation. Unlike routine CT or MRI, enterography can display mural changes along with perienteric inflammatory changes with much better resolution. These studies are more accurate than the standard small bowel follow-through or enteroclysis.[10-13] Magnetic resonance elastography is increasingly recognized as a modality for detecting and staging hepatic fibrosis and nonalcoholic fatty liver disease (NAFLD). The use of magnetic resonance elastography may negate the need for liver biopsy in some patients.[14] Alternatively, fibrosis detected on sonographic elastography correlates well with that detected by MRI. However, higher body mass index, presence of ascites, and small intercostal distance limit the utility of ultrasound elastography.[15] The combination of positron emission tomography (PET)/MRI can be very useful to evaluate for focal liver lesions and liver metastasis of various childhood neoplasms.[16]

Ultrasonography of the liver and biliary tract identifies hepatic parenchymal disease, biliary stones, or congenital abnormalities such as choledochal cyst. Intussusception, pyloric stenosis, and acute appendicitis are particularly amenable to ultrasonographic diagnosis. In addition, Doppler flow analysis has significantly aided the preoperative and postoperative evaluation of liver transplant recipients by identifying congenital vascular anomalies and postoperative vascular thromboses.

Radionuclide Scanning

Radionuclide scanning is helpful when patients in the ICU have pulmonary aspiration, gastrointestinal bleeding, intraabdominal abscesses, or cholestasis.

Gastroesophageal reflux and the rate of gastric emptying can be measured with liquid-phase gastroesophageal scintigraphy.[17] Technetium-99 (^{99}Tc) sulfur colloid is mixed with formula or another enterally administered liquid. When there is a scan above and below the diaphragm in 30- to 60-second windows during the first postprandial hour after isotope administration, the number of reflux episodes, the height of the reflux column, and the rate of gastric emptying are quantitated. A 4- to 6-hour delayed scan of the lungs determines whether pulmonary aspiration of that meal has occurred.[18]

Three techniques are used to aid in the diagnosis of gastrointestinal bleeding. ^{99}Tc sulfur colloid and ^{99}Tc-labeled red cells are used in patients with continuous or intermittent bleeding. The advantage of sulfur colloid is that less than 0.1 mL/min of blood can be detected. Bleeding in a spot near the liver or spleen, however, may be obscured by high levels of activity in those organs. Tagged red blood cell scans detect intermittent bleeding by means of delayed scans, but migration of blood down the gastrointestinal tract over time may preclude exact localization. ^{99}Tc pertechnetate scanning does not require active bleeding to localize a Meckel diverticulum. The isotope is concentrated by gastric mucosa, and if a scan reveals an ectopic focus, a Meckel diverticulum can be suspected. Scan results are negative in the 15% of diverticula not containing gastric mucosa. A variety of non-Meckel lesions (most of which require surgical correction) cause false-positive results on pertechnetate scans. The sensitivity of the scan can be increased when acid suppression is given prior to scanning.

Resolution of hepatobiliary scans has improved dramatically since the

introduction of derivatives of ^{99}Tc iminodiacetic acid. Scanning can now document cholecystitis when there is no gallbladder uptake or biliary obstruction when there is no excretion into the bowel. Other entities such as biliary leaks or cystic lesions of the biliary tree can also be documented. Furthermore, delayed or reduced hepatocyte uptake can confirm impaired hepatocellular function.

Intraabdominal abscesses and inflammatory intestinal lesions can be localized with radioscintigraphy.[19] Leukocytes are extracted from the patient, tagged with a radioisotope in vitro, and reinjected. Scanning of the area in question is then performed. Technetium hexamethyl propyleneamine oxime (HMPAO) has replaced indium because of improved resolution of HMPAO scans and because HMPAO scans can be completed within 4 hours rather than 72 hours.

Testing for Occult Blood Loss

Occult blood loss is generally determined with the Hemoccult or Gastroccult test; these are modifications of the guaiac test.[20,21] They work because hemoglobin oxidizes the reagent to a blue product. The Hemoccult Sensa (Beckman Coulter, Inc., Brea, California) slide detects as little as 2 to 3 mL of stool blood loss per day. This slide is virtually 100% sensitive when blood loss equals 10 mL/day.[8]

In the stomach, blood can be denatured, and this can lead to false-negative results. Gastroccult, which contains borate-buffered reagent, significantly improves the sensitivity for testing gastric contents. (Urine test tapes should never be used for gastrointestinal occult blood testing because they are too sensitive.) Therefore even physiologic quantities of enteric blood loss (<1 mL of blood per day) will yield positive results.

Stool pH and Reducing Substances

Excessive enteral carbohydrate loads may worsen preexisting diarrhea in critically ill children. Carbohydrate malabsorption can be assessed with the measurement of reducing sugars and pH of stool. The two tests should always be used in conjunction because colonic transit time and the quantity or type of colonic flora affects either of these tests. Malabsorbed sugars appear in feces when colonic transit is sufficiently rapid and are detected by Clinitest tablets or reagent strips; sugar more than 0.5 mg/100 mL of stool water suggests malabsorption. If the malabsorbed dietary sugar is primarily sucrose, a nonreducing sugar, the Clinitest result is negative unless the stool is first hydrolyzed with hydrochloric acid. Stools can be negative for reducing sugars despite carbohydrate malabsorption if colonic transit is slow enough to permit complete bacterial fermentation. In such an event, pH of fresh stool (measured by nitrazine paper) is consistently below 5.5. The pH of samples not tested for several hours, however, tends to rise over time as short-chain fatty acids generated from sugar fermentation are further metabolized.

The Intensive Care Unit as a Satellite Laboratory Facility

Regulations of The Joint Commission prohibit testing for occult blood loss or stool testing by anyone other than an individual certified in accordance with the Clinical Laboratory Improvement Act (CLIA). Thus for many pediatric critical care units,

bedside testing has moved from the bedside to the clinical laboratory. Turnaround time for measuring occult blood in stool has risen from seconds to hours. Furthermore, when fecal samples are sent to the clinical laboratory for measurement of reducing sugars and pH, results are meaningless insofar as bacterial metabolism of sugars continues ex vivo in these samples between the times of collection to the time of testing. Critical care units wishing to perform reliable fecal testing on site must train a cohort of staff in common bedside tests and obtain CLIA certification for each staff member. Furthermore, just as many ICUs have chosen to comply with CLIA regulations and have established approved satellite laboratory facilities to measure blood gases or serum electrolytes, they can extend the scope of their laboratory activities to include bedside gastroenterologic testing.

Life-Threatening Complications of Gastrointestinal Disorders

Systemic

Central Line–Associated Bloodstream Infection

Children with intestinal failure who are reliant on parenteral nutrition through a central line are at high risk of central line–associated bloodstream infections (CLABSIs) because of the presence of an indwelling catheter and the generalized inflammation and reduced mucosal barrier of their gut. CLABSIs are the number one cause of mortality among this patient group. These children are frequently admitted to the pediatric intensive care unit with septic shock. Children who are younger have a shorter segment of viable bowel (<50 cm), and those receiving a higher dose of parenteral lipids seem to be at increased risk of CLABSIs. The most common bacteria causing these infections are enteric gram-negative organisms such as *Klebsiella* species and *Enterobacter* species. *Enterococcus* species and *coagulase-negative staphylococci* can also be commonly seen, as can *Candida* species. As such, therapy should start with broad-spectrum gram-negative and gram-positive coverage with addition of an antifungal if this is a concern, with narrowing of coverage as soon as species identification and susceptibility testing allow. A goal of treatment for these children is often to salvage their central line, as their life depends on their ability to receive parenteral nutrition, and they may have limited venous access. Loss of vascular access is one of the few indications for small bowel transplant in these patients. Ethanol locks are an inexpensive method to improve infection clearance rates and increase line salvage rates both in the pediatric intensive care unit and in the outpatient setting and may be used in both a treatment and prophylactic approach. Ethanol locks are preferred over antibiotic locks due to their ability to eradicate biofilms and to minimize the evolution of resistant bacteria[22-24] (see also Chapter 110).

Esophagus

Congenital Esophageal Anomalies

Esophageal atresia and tracheoesophageal fistula are true neonatal emergencies. With an incidence of 1 in 3000 live births, they are among the most common

congenital anomalies of the esophagus. Five anatomic varieties exist in the following descending order of frequency: (1) blind proximal esophageal pouch with distal esophagus originating at the tracheobronchial junction (80%), (2) blind proximal esophageal pouch with blind distal esophageal pouch (8%), (3) uninterrupted esophagus with H-type tracheoesophageal fistula (4%), (4) proximal esophagus fistulizing into trachea with blind distal esophageal pouch (2%), and (5) interrupted esophagus with both proximal and distal esophagus communicating with trachea (1%). The embryogenesis of this disorder is unknown, but other cardiovascular, gastrointestinal, skeletal, or urogenital anomalies are present in 50% of cases.

Infants with a blind proximal esophagus have excessive salivation, respiratory distress, and cyanosis. Diagnosis of blind proximal esophagus can be made by the failure to pass a nasogastric tube into the stomach. Complete atresia leads to a gasless lower gastrointestinal tract. An H-type fistula is sometimes seen on contrast radiography or esophagoscopy, but bronchoscopy is usually the most sensitive diagnostic tool.

Treatment is surgical. A simple fistula can be ligated, and a short atresia can be repaired primarily. Long atresia, however, may require staged treatment with initial esophagostomy and gastrostomy and subsequent definitive repair after internal or external traction is applied. Circular myotomy of the esophagus reduces anastomotic tension. Occasionally a gastric tube procedure or colonic interposition is required.

Caustic Injury to the Esophagus

Despite widespread efforts by poison control centers to publicize the dangers of household caustics, thousands of inadvertent ingestions occur annually; most occur in children younger than 5 years. Crystalline products produce greater damage to the hypopharynx and upper airway because of prolonged mouth contact and a smaller volume reaching the esophagus. Most household cleaners have been reformulated to contain less lye, but pure liquid lye can be purchased if desired. Its resemblance to milk leads to numerous inadvertent ingestions by children (see Chapter 128).

Tissue damage can be caused by either strong alkali or acid. Deep esophageal burns are more common after alkali ingestion. Alkalis produce rapid liquefaction of esophageal tissue, and burns can range from first to third degree in depth.[25] An intense inflammatory infiltrate develops, and blood vessels thrombose to produce ischemic necrosis. Perforation may occur within hours or days. Strictures can occur weeks to years after ingestion.[26] Esophageal burns occur infrequently after acid ingestion, but gastric or duodenal erosions have been reported.

Symptoms that predominate are chest pain and the inability to swallow secretions. Children with upper airway damage often exhibit stridor. When mouth burns are present, the chances of esophageal injury are 75%.[1] Conversely, 25% of patients with significant esophageal burns have no pharyngeal or mouth involvement.[25]

Treatment of severe stridor should be directed toward establishing an airway, and emergency tracheostomy should be contemplated. Upper endoscopy within 24 hours is advisable. If burns are minor, no further therapy is necessary, and patients are at low risk of sequelae. Third-degree burns require ongoing intensive care, though. The role of antibiotics and steroids remains controversial.[27] When third-degree burns are endoscopically evident, a nasogastric tube should be positioned with endoscopic guidance. This tube will enable early feeding and serve as a guide for future

dilations if they become necessary. Some surgeons have advocated early placement of gastrostomies and esophageal stents in patients with third-degree burns.

Esophageal Foreign Bodies

Children can swallow a variety of metallic, wooden, or plastic foreign bodies in a myriad of shapes and sizes. All that are lodged in the esophagus require urgent removal (within 24 hours). Even more urgent endoscopic retrieval is required for button batteries or pennies minted after 1983 that are lodged in the esophagus because both are caustic to esophageal mucosa and may cause damage within 1 to 4 hours. The preponderance of evidence suggests that once a battery has escaped the esophagus, complications from an unretrieved battery are rare.[28]

Similarly, pennies minted after 1983 are predominantly zinc based and can be nearly as caustic within the esophagus as button batteries. No published epidemiologic studies are available on which to base the approach to zinc-based pennies within the stomach or small intestine.

Gastroesophageal Reflux

Several antireflux barriers exist in the region of the lower esophageal sphincter. Beyond intrinsic myogenic tone, barriers such as the cardioesophageal angle, the abdominal esophagus (that acts as flutter valve), the mucosal rosette of the sphincter (that acts as a choke valve), and the diaphragmatic crura themselves act to prevent reflux of gastric contents. A complex set of factors, including hormonal changes, anatomic relationships, increased or decreased sensitivity to neurotransmitters, and CNS derangements, act to produce inappropriate sphincter relaxation (usually transient), which leads to most episodes of gastroesophageal reflux. With the advent of more sophisticated otolaryngologic procedures such as the laryngotracheoplasty and slide tracheoplasty, prevention of gastroesophageal reflux is of utmost importance to facilitate surgical healing. Some surgeons advocate the use of aggressive acid suppression postoperatively because acid-induced damage can result in significant cicatrix formation at the site of laryngotracheal surgery.

Life-threatening events such as apnea and pulmonary aspiration are sometimes attributed to reflux. The relationship between infantile apnea and reflux remains in question,[29] but both human and animal data suggest that reflux can occasionally be associated with obstructive breathing patterns. Severe pulmonary aspiration of refluxed material can also take place. A number of protective mechanisms such as an active gag reflex, cough reflex, and laryngospasm protect against aspiration,[30] but these reflexes may be lost under special circumstances such as obtundation. Symptoms of obstructive apnea often include a brief episode of stridor accompanied by a struggle to breathe, a change in skin color to red or purple, and finally cyanosis and cessation of respiratory effort. Patients who have aspirated massive amounts of fluid become tachypneic and dyspneic shortly after the meal. Food or formula is often found in the nares or mouth, and cough may be present. The diagnostic modality most helpful in documenting a temporal relationship between apnea and acid reflux is 24-hour esophageal reflux monitoring combined with simultaneous electrocardiography, pneumography by chest wall impedance, pneumography by nasal thermistor, pulse oximetry, and end-tidal CO_2 measurement. Aspiration is often difficult to document, but the presence of a new infiltrate on chest x-ray films

and a consistent clinical history provide strong circumstantial evidence. If repeated aspiration is suspected, an upper gastrointestinal tract series may reveal gastroesophageal reflux and immediate aspiration of barium; however, aspiration of gastroesophageal refluxate that occurs minutes or hours after a feeding may be missed with contrast radiography. A milk scan may be more sensitive than radiography for documenting this type of aspiration. Children who are not fed orally may nevertheless aspirate oral secretions. The scintigraphic *salivagram* is performed with the placement of a drop of saline containing ^{99m}Tc sulfur colloid on the tongue.[31] Subsequent imaging permits observation of its handling. The appearance of isotope in the trachea and bronchi confirms aspiration.

When recurrent aspiration is suspected but not confirmed noninvasively, bronchoscopy with bronchoalveolar lavage may support the diagnosis by returning fluid-containing lipid-laden alveolar macrophages.[32] Aspiration during swallowing and aspiration of refluxed gastric contents cannot be distinguished by this method in patients who are fed orally.

Although some clinicians view one episode of reflux-induced aspiration or apnea as an absolute indication for fundoplication, the decision to perform fundoplication should be based on the severity of the initial episode, underlying conditions that predisposed the child to the episode, risk for recurrence, and the expected natural history of reflux for a particular patient. In other words, some patients may be successfully managed with pharmacotherapy (a proton pump inhibitor with or without a prokinetic agent such as metoclopramide or erythromycin).

For patients with neurologic impairment, excessive drooling can lead to chronic aspiration, pneumonia, and difficult airway control; however, there are several treatment options for this issue. The first, and most commonly used, is glycopyrrolate; however, due to its anticholinergic properties, it is often not tolerated or leads to unacceptable thickening of secretions. Another option is injection of botulinum toxin A by a pediatric otolaryngologist or interventional radiologist. Various studies have shown that approximately 60% of patients improve after these injections, and if there is improvement, the patient may benefit from subsequent injections. Male sex and cerebral palsy were associated with an increased positive response. The major side effect for botulinum toxin injection is dysphagia.[33] Finally, some patients who are refractory to more conservative management may benefit from surgical intervention by otolaryngology, specifically a submandibular gland excision, ligation of submandibular and parotid ducts (commonly known as a *drool* procedure), and, in the most extreme of cases, a laryngotracheal separation.[34]

Stomach and Duodenum

Gastric Volvulus

Acute gastric volvulus may be of two types. When the whole stomach revolves about its long axis, organoaxial volvulus has occurred. When the fundus and pylorus exchange positions, the volvulus is mesenteroaxial. Predisposing factors include paraesophageal hernias or eventration of the diaphragm.

Because a closed obstruction has occurred, the patient is unable to vomit despite severe pain, distention, and retching. Plain radiographs reveal a markedly distended stomach with air-fluid levels, and contrast radiography may reveal cardioesophageal junction obstruction. An immediate operation is indicated.

Gastric Ulcer

Whereas some authors suggest that duodenal ulcers outnumber gastric ulcers in childhood,[35] others have reported that young children are more likely to have gastric ulcers. Most gastric ulcers lie at the junction of gastric fundus and body. Those high in the fundus are usually related to stress. Antral ulcers are often the result of use of nonsteroidal antiinflammatory drugs (NSAIDs).

A well-recognized complication of severe illness requiring admission to the ICU is stress ulceration of the stomach. Bleeding becomes an important source of morbidity and mortality in patients with burns and trauma, as well as in those who have undergone major operations or have systemic disease. Prophylaxis against bleeding is common in the ICU setting. Antacids, H_2-receptor antagonists (H_2RA), proton pump inhibitors such as lansoprazole and pantoprazole, and sucralfate are most often used. Unfortunately, elevation of gastric pH by antacids and H_2RA removes one barrier against bacterial colonization and may increase the risk of pneumonia with organisms colonizing the stomach.[36] Large controlled trials, however, have failed to confirm this concern. Sucralfate is equally effective as prophylaxis against bleeding but does not affect gastric pH. If sucralfate is given concurrently with antacids or acid-suppressing medications, its efficacy will be reduced because it requires an acidic environment for optimal effect. Furthermore, sucralfate administered in close temporal proximity to other enterally administered medications may reduce their bioavailability by binding with them within the intestinal lumen (see also Chapter 98).

Most patients with gastric ulcers are hypochlorhydric rather than hyperchlorhydric, because exposure to detergents or toxins such as NSAIDs, pepsin, bile salts, or ethanol erodes the gastric barrier to back-diffusion. A second consistent finding among patients with gastric ulcers is delayed gastric emptying, which may be an epiphenomenon or central to the pathogenesis of ulcers. The association between *Helicobacter pylori* infection and chronic gastritis as well as gastric and duodenal ulcers is now well established.

Clinical features of gastric ulcer resemble those of duodenal ulcer. Pain predominates and is epigastric in location but usually follows eating more closely. Nausea and vomiting may occur. Milk or antacids relieve the pain. The two complications of gastric or duodenal ulceration most commonly requiring intensive care are perforation and bleeding. Perforation, requiring immediate surgical intervention, produces exquisite pain and rapid development of peritoneal signs in patients without immunosuppression.

Hematemesis heralds gastric ulcer bleeding and may be as massive as that of duodenal ulcer. Careful, repeated assessment of vital signs and prompt restoration of circulating blood volume by large-bore venous catheters are essential. Saline solution or epinephrine gastric lavage through a large sump tube is mandatory. *Iced* saline lavage offers no advantage and excessively depresses core temperature.

Efforts should also focus on reducing gastric acid production with a parenteral proton pump inhibitor.[37] Continuous intravenous vasopressin infusion, commonly used for control of variceal hemorrhage, reduces arterial flow through the splanchnic bed. Intravenous administration of somatostatin or its synthetic, active octreotide moiety, has been effective in stemming variceal hemorrhage and may work for other causes of bleeding. In addition to their hemodynamic effects, they inhibit gastric acid

production.

When the patient's condition is stable, endoscopy may be performed to localize the ulcer. Endoscopic therapy may then be performed on actively bleeding ulcers or those with visible vessels (which tend to rebleed). Ulcer beds may be photocoagulated, electrocoagulated, or thermocoagulated. They may also be injected with hemostatic agents such as epinephrine. If nonsurgical techniques fail to stop the bleeding, one of several surgical options (including ulcer oversewing or resection, variations of gastric drainage procedures, and vagotomy) must be performed. Fortunately, successful pharmacologic and endoscopic therapies have precluded the need for these surgical therapies in all but the rarest circumstances.

Duodenal Ulcers

The incidence of duodenal ulcer in childhood is unknown. A large series completed before the popularization of endoscopy suggested an incidence of 4.4 cases per 10,000 pediatric patients per year, which is, no doubt, an underestimation.[35] The male predominance seen among adults is present only among postpubertal children. The risk for patients with blood group O is 1.3 times that expected.

A number of factors have been implicated in the pathogenesis of duodenal ulcers. Unquestionably, excessive acid production plays a major role. Some factors leading to hypersecretion include excessive gastrin or histamine production and increased vagal tone. Approximately half of patients with ulcers are also hyperpepsinogenemic, and their mucosal integrity may therefore be suboptimal.[38] Infection with *H. pylori* reduces the ulcer healing rate and increases the recurrence rate.[39] Although approximately 90% of adult duodenal ulcers are associated with *H. pylori* infection, only about 50% of pediatric duodenal ulcers are related to *H. pylori*.[40] The effects of diet and stress have been minimized in the literature.

Symptoms in children are similar to those of adults. Epigastric pain occurs after meals and often awakens the child from sleep. Vomiting occurs in 40% of patients.

The major life-threatening complications are perforation and hemorrhage, which lead to a *surgical* abdomen and shock, respectively. Abdominal plain films reveal free air if perforation has occurred. Hemorrhage presents as hematemesis, hematochezia, or melena. Endoscopy is the most sensitive tool to localize the ulcer and to characterize the risk for rebleeding. Ulcers with visible vessels in the crater are at greatest risk of recurrent hemorrhage and may require endoscopic coagulation. Principles of management are identical to those for gastric ulcer. *H. pylori* is increasingly resistant to conventional antibiotics such as metronidazole and clarithromycin.[41] Triple therapy with a proton pump inhibitor, amoxicillin, and either clarithromycin or metronidazole for 10 to 14 days is currently recommended; however, in areas with high clarithromycin resistance, clarithromycin susceptibility testing is first recommended.[42]

Small Intestine and Colon

Malrotation

In embryonic life, the cecum and ascending colon are located on the left side of the abdomen and the small bowel is on the right. During gestation, the midgut transiently protrudes into the umbilicus and rotates 270 degrees, and the cecum is

moved to the right lower quadrant and the duodenojejunal junction to the left upper quadrant. Incomplete rotation is of little consequence unless midgut volvulus, which can be a catastrophic event, occurs.

Some patients with malrotation experience partial duodenal obstruction because of extrinsic compression by mesenteric bands. Chronic diarrhea and protein-losing enteropathy may be seen, among others, without complete obstruction.

Clinical features of obstructing volvulus include severe abdominal pain, bilious vomiting, and abdominal distention. Surgical treatment requires a Ladd procedure, in which mesenteric bands are divided and the bowel is returned to its fetal position. Failure to promptly relieve the volvulus leads to ischemic necrosis of all of the gut supplied by the superior mesenteric artery (proximal jejunum to midtransverse colon). Short gut syndrome results from resection of the affected intestine.

Necrotizing Enterocolitis

Necrotizing enterocolitis is primarily a disorder of premature infants, affecting 2.5% of neonatal patients in the ICU but only 0.2% of all infants. The most common areas involved are the ileum and proximal colon, but any part of the intestinal tract may be affected. Its pathogenesis is unknown, but bowel ischemia, feeding of hyperosmolar formula, rapid advancement of feeding,[43] reduced immune surveillance, and population of the bowel by excessive quantities of enterotoxin-producing bacteria[44] may all play a role.

The classic clinical features are abdominal distention, bilious vomiting, and bloody stools, but symptoms are more subtle in some infants. If left unrecognized, necrotizing enterocolitis may become fulminant, leading to shock, disseminated intravascular coagulation, and apnea.

An abdominal plain film showing pneumatosis intestinalis, hepatic portal air, or both may confirm the diagnosis of necrotizing enterocolitis. Because the pathogenesis is unknown, treatment must be symptomatic. In most centers, feedings are discontinued for 48 hours to 2 weeks depending on the severity of symptoms. Fluid resuscitation and broad-spectrum parenteral antibiotics are the basis of medical therapy. Surgical resection is reserved for severe cases when medical management fails and gangrenous bowel develops. Data have emerged suggesting that changes in the neonatal fecal microbiome or production of excessive quantities of volatile organic acids are early markers of necrotizing enterocolitis (NEC); however, the ability to detect these entities is not yet practical for the clinician at the bedside.[45,46]

Perforation may sometimes be managed successfully in infants with very low birth weight, with simple peritoneal drainage performed with the infant under local anesthesia.[38]

Low Cardiac Output Syndrome

Advancements in surgical techniques have led to significant improvement in morbidity and mortality after pediatric cardiothoracic surgery. However, patients remain at risk for decreased cardiac output and impaired systemic oxygen delivery, especially in the early postoperative period. The drop in cardiac output after cardiac surgery is characterized as low cardiac output syndrome (LCOS). LCOS is defined as an inability of the heart to provide adequate oxygen delivery to meet the body's

metabolic demand. It is primarily due to transient myocardial dysfunction compounded by acute changes in myocardial loading. Cardiopulmonary bypass, along with residual cardiac abnormalities, may further aggravate the underlying low cardiac output state.[47,48] Although there are several manifestations of this clinical constellation beyond the scope of this chapter, it is important to recognize its clinical signs and symptoms (see Chapter 38). Systemic venous congestion may be observed in the gastrointestinal tract. Manifestations include hepatomegaly, ascites, and peripheral edema. Hypoperfusion to the liver can result in hepatic insufficiency and may lead to coagulopathy if severe enough. Furthermore, intolerance to enteral feeding may be evident in these patients with LCOS and central venous hypertension. Feeding difficulties may be further compounded by high-dose inotropes and narcotic infusions. These patients often require parenteral nutrition. Complications such as mesenteric ischemia or necrotizing enterocolitis may be observed in rare cases and are often fatal.[49,50]

Food Allergy

Food allergy can be defined as a reproducible, immunologically mediated reaction to an ingested food protein. Pathogenic events can be classified according to the schema of Gell and Coombs as type I (reaginic, immediate hypersensitivity reaction), type II (cytotoxic reaction), type III (immune-complex reaction), or type IV (delayed hypersensitivity reaction).

Manifestations may be systemic[51] or confined to the gastrointestinal tract.[52] Life-threatening systemic manifestations include acute urticaria and anaphylaxis.[53] Gastrointestinal reactions, which are sometimes severe, include allergic enteritis, allergic colitis, and celiac crisis.

Acute urticaria is usually easily recognized by the classic wheal and flare cutaneous lesions often accompanied by laryngeal edema and angioedema. Anaphylaxis is an antigen-triggered immune reaction that leads to vascular collapse and bronchospasm (see also Chapter 106).

Food protein–induced enteropathy is characteristically a disorder of the infant and toddler. The small bowel develops patchy villous atrophy. Symptoms and signs range from those of malabsorption and enteric protein loss to those of profound diarrhea and shock. Colitis caused by food protein sensitivity is seen most commonly among infants younger than 6 months.[52] Bloody, mucoid diarrhea develops several days or weeks after their first oral antigen challenge. Even though this colitis usually takes a benign course, it may be severe enough to mimic necrotizing enterocolitis.

Although some do not categorize gluten enteropathy as true food allergy, it shares enough features with allergy to justify inclusion with this category of disorders.[52] Celiac crisis is a rare, life-threatening complication that may occur among untreated patients with a large gluten load or in treated patients as a result of dietary indiscretion. Massive fluid and electrolyte loss leads to shock.

The cornerstone of long-term therapy is elimination of the offending food, but emergency measures are also required. Immediate administration of epinephrine and corticosteroids is essential in the treatment of anaphylaxis. Urticaria may require the administration of antihistamines, corticosteroids, and epinephrine. Steroid use also seems to benefit patients in celiac crisis. Rapid administration of crystalloid or colloid is crucial in the management of any of these reactions.

Hemolytic-Uremic Syndrome

The hemolytic uremic syndrome may occur in epidemic or sporadic forms (see Chapter 75). It is frequently preceded by enteric infection with bacterial[54] or viral pathogens. Infection with Shiga toxin–producing *Escherichia coli* precedes a high number of cases.[55,56] Instigating factors, such as bacterial verotoxin, cause endothelial damage in the kidney, liver, heart, brain, adrenal glands, and gastrointestinal tract.

Clinical features include a prodrome of abdominal pain, vomiting, and diarrhea, which may be bloody. Patients may have endoscopic, radiographic, or histologic evidence of ischemic bowel disease. As gastrointestinal symptoms improve, hemolytic anemia and thrombocytopenia rapidly appear with associated symptoms of petechiae, epistaxis, gingival bleeding, and pallor. Subsequently, patients become oliguric, hypertensive, and azotemic. Pancreatitis may further complicate the clinical course. Seizures and altered mental status may occur.

The intensivist caring for children with acute, hemorrhagic colitis must pay exceptional attention to fluid balance, hemogram, and renal function studies. Any sudden change in hemoglobin, platelet count, blood urea nitrogen, or urine output should be considered a potential sign of hemolytic uremic syndrome. In the absence of hypovolemic shock, fluid intake should be curtailed if hemolytic uremic syndrome is documented. In the event of severe renal insufficiency, dialysis is necessary.

Atypical hemolytic uremic syndrome (aHUS) presents similarly to hemolytic uremic syndrome with hemolytic anemia, thrombocytopenia, and renal dysfunction but is usually not associated with a prior bacterial infection or diarrhea. In aHUS, dysregulation of the complement cascade leads to uncontrolled complement activation. Patients were previously treated with plasma exchange; however, the morbidity and mortality rates remained high. Eculizumab, a monoclonal antibody that targets C5 to block the complement cascade and prevent formation of the terminal complement complex, has been used in children with aHUS with better results than plasma exchange.[57]

Inflammatory Bowel Disease

Crohn disease and ulcerative colitis are chronic, relapsing disorders without known causes. The transmural inflammation of Crohn disease may affect any portion of the alimentary tract in a patchy distribution, whereas the inflammation of ulcerative colitis is confined to the mucosa of the colon. The latter always involves distal colon, and its contiguous inflammation extends for varying distances from the rectum. The two entities are different enough to usually permit accurate categorization, but there is sufficient overlap in symptoms and distribution that the diagnosis is indeterminate in 15% of cases. Table 97.1 summarizes the clinical, radiographic, endoscopic, and histologic differences between the two.

TABLE 97.1

Differential Diagnosis Between Ulcerative Colitis and Crohn Disease

Feature	Ulcerative Colitis	Crohn Disease
Relative Incidence of Symptoms		
Rectal bleeding (gross)	Common	Rare
Diarrhea	Often severe	Moderate or even absent
Pain	Less frequent	Almost always

Anorexia	Mild or moderate	Can be severe
Weight loss	Moderate	Severe
Growth retardation	Usually mild	Often pronounced
Extraintestinal manifestations	Common	Common
Involvement		
Small Bowel Involvement		
Extensive	—	10%
Lower ileum	5%-10%	90%
Colon	100%	75%
Rectum	95%	50%
Anus	5%	85%
Distribution of Lesions	Continuous	Segmental
Radiologic Features	Superficial ulcers, loss of haustration, no skip areas, shortening	Serpiginous ulcers, thumbprinting, skip areas, string sign
Pathologic Changes	Diffuse mucosal disease	Focal transmural disease, granulomas
Response to Treatment		
Steroids and sulfasalazine	75%	25%-75%
Parenteral nutrition and elemental diets	Poor	Very good for small bowel
Azathioprine and 6-mercaptopurine	Good in selected cases	Good in selected cases
Surgery	Excellent	Fair or poor
Course		
Remissions	Common	Common
Relapse after surgery	Rare	5%-100%
Cancer risk	High in pancolitis	Slight

Modified from Silverman A, Roy CC, editors: *Pediatric clinical gastroenterology*. ed 3. St. Louis: Mosby; 1983:354.

The cause of these disorders remains speculative. Clearly, genetic factors predispose patients to one or the other, but environmental factors also appear to play a role.[58] Etiologic factors considered important over the years have included psychogenic predisposition, food allergies, infectious processes, immunologic deficiency, and immunologic hyperreactivity.

Presenting signs and symptoms include abdominal pain; bloody or nonbloody diarrhea; anorexia; abdominal mass; and extraintestinal manifestations, such as weight loss, fever, arthritis, or erythema nodosum. Patients are often anemic and hypoproteinemic, and they may show hematologic or biochemical signs of acute-phase response. The radiographic and histologic features are typical (see Table 97.1).

The cornerstone of achievement of remission has long been corticosteroids. Enteral feedings are emerging as an important component of achieving remission.[59] 5-Aminosalicylic acid (5-ASA) is effective for maintenance therapy for mild ulcerative colitis and Crohn colitis. Evidence is less compelling that 5-ASA is effective in small intestinal Crohn disease. Immunosuppressants, such as 6-mercaptopurine (6-MP) and methotrexate, have been used for Crohn disease, and 6-mercaptopurine also seems effective in the treatment of ulcerative colitis. Biological agents have revolutionized the therapy of Crohn disease.[60] Infliximab, a monoclonal antibody against tumor necrosis factor, has shown dramatic efficacy against Crohn disease in up to 75% of patients. A second anti–tumor necrosis factor (TNF) agent, adalimumab, can be given subcutaneously. New biologic agents such as vedolizumab, which binds to integrin alpha4 beta (LPAM-1), target a different pathway and are being used when first-line biologics fail.

Severe complications may also be directly attributed to therapy. Pancreatitis is associated with 5-ASA and 6-MP. In addition, bone marrow suppression as well as hepatitis have been observed with 6-MP. Infliximab is associated with lymphoid malignancies, and the concomitant use of 6-MP with infliximab may synergistically

heighten the risk of lymphoma. Patients who take infliximab should also be observed for possible anaphylaxis. Patients with Crohn disease are at increased risk of secondary hemophagocytic lymphohistiocytosis (HLH); there is an increased risk associated with 6-MP use as well as primary Epstein-Barr virus infection.[61] Patients with HLH often come to the attention of intensivists because of their high risk of infection as well as pulmonary, hematologic, and hepatic complications (see also Chapter 106). Hepatosplenic T-cell lymphoma and other nongastrointestinal malignancies have been associated with the combined use of anti-TNF alpha agents and 6-MP, with males being at higher risk.[62]

Complications most likely to require an intensivist's attention are perforation, toxic dilation of the colon, and fulminant colitis. A patient whose bowel has perforated exhibits decreased bowel sounds and abdominal rigidity. Point and rebound tenderness may be present. Abdominal x-ray films may reveal free intraperitoneal air. Most perforations in Crohn disease produce intraabdominal abscesses, but peritonitis does not. Some abscesses, however, can contaminate the peritoneum. Free colonic perforation tends to occur among patients with ulcerative colitis. Toxic dilation and fulminant colitis are also more common with ulcerative colitis but may occasionally occur in Crohn colitis. Because management of severe inflammatory bowel disease frequently includes immunosuppression with high-dose corticosteroids, cyclosporine, or azathioprine, some of the signs and symptoms of perforation may be masked in the population most likely to have such complications. Factors such as patient immobility, antiperistaltic drugs, rigorous cathartic use, and electrolyte imbalance are frequently associated with toxic dilation of the colon. Patients initially exhibit massive abdominal distention and pain. X-ray films reveal an increased transverse colonic diameter. The patient's status is observed through careful monitoring of vital signs, physical examination, and repeated abdominal radiographs. Management includes giving nothing by mouth during nasogastric tube suction and inserting a rectal tube for decompression. Frequent position changes may aid in redistributing air distally. Fluid and electrolyte balance is aggressively maintained, and broad-spectrum parenteral antibiotics are given. Efforts at medical management should not exceed a few hours because of the extreme risk of perforation. Clinical decompensation or perforation is an indication for urgent surgical resection of the colon.

Fulminant colitis is characterized by fever, shock, severe abdominal pain, 10 or more bloody stools per day, and abdominal tenderness. Broad-spectrum antibiotics, intravenous steroids, immunosuppressants such as cyclosporine,[63] red blood cell transfusion, and fluid replacement are the mainstays of treatment for fulminant colitis. Small, uncontrolled series have also suggested that infliximab may be beneficial for fulminant colitis.[64] Failure to respond within a few days, however, warrants colectomy.

Distal Intestinal Obstruction Syndrome

Distal intestinal obstruction syndrome (DIOS) is unique to the cystic fibrosis (CF) population. Affected patients present with signs of bowel obstruction including abdominal pain, abdominal distention, and emesis. DIOS is characterized by a fecal mass in the ileocecum. The obstruction can be either partial or complete and the onset chronic, subacute, or acute. The CF bowel is more prone to obstruction due to impaired mobility as well as abnormal composition of the intraluminal contents.

Patients at increased risk of DIOS include those with previous abdominal surgeries, a history of meconium ileus, pancreatic insufficiency, and having undergone lung transplant. Patients with incomplete obstruction can be managed with osmotic agents such as polyethylene glycol 3350. Gastrografin can be administered orally or as an enema; however, its administration is not without risk of hypovolemic shock (due to fluid shifts) and intestinal perforation.[65] Exploratory laparotomy with or without bowel resection is limited to the most severe cases; in one case series, the rate of surgical intervention was approximately 12.5%.[66]

Hirschsprung Disease

Hirschsprung disease occurs in 1 in 5000 live births. It may be the result of incomplete craniocaudal migration of neural crest elements, but some investigators believe that ganglion cells degenerate after migration. Aganglionosis may involve as little as a few centimeters or the entire colon and small bowel (in rare cases). Total colonic Hirschsprung disease occurs in clusters in some families with the risk being 21% in those families.[67] The inheritance of familial Hirschsprung disease appears to be polygenic, with mutations in several loci of the rearranged during transfection (RET) protooncogene being associated with autosomal dominant Hirschsprung disease that is most commonly the short-segment type. Mutations of the endothelin receptor type B gene are more likely to be observed in long-segment, autosomal recessively transmitted Hirschsprung disease. Other gene mutations may also modify the expression of the disease.[67]

The most common feature of Hirschsprung disease is the failure to pass meconium in a timely fashion after birth; 94% of infants with Hirschsprung disease pass their first stool beyond 24 hours of life. Most patients with Hirschsprung disease are constipated but cannot pass flatus. If their condition is undiagnosed during the first months of life, they may fail to thrive.

Physical findings include abdominal distention and an empty rectum on digital examination. Barium enema often reveals a narrow-caliber aganglionic distal colon; a transition zone; and a dilated, ganglionic proximal colon. It is essential that the barium enema be performed without prior enema preparation to preserve the transition zone. Absence of the anal-inhibitory reflex on anorectal manometry is suggestive. The diagnosis is confirmed histologically by rectal biopsy of the distal rectal mucosa where hypertrophic nerve trunks but no ganglion cells are found. Acetylcholinesterase staining of the specimen improves the diagnostic yield by enhancement of the abnormal nerve trunks.

In some children the course of Hirschsprung disease is punctuated by episodic, severe enterocolitis, which leads to copious, bloody diarrhea, fever, and shock. The intensive care of patients with enterocolitis should emphasize reconstitution of circulating blood volume with crystalloid, colloid, and red blood cells. Broad-spectrum parenteral antibiotics are advisable. After the patient's condition is stabilized, urgent decompressive enterostomy is indicated. Pull-through operations are usually performed after several months. Enterocolitis in the remaining ganglionated intestine may occur even in some patients who have undergone a pull-through operation.[68]

Acute Colonic Pseudo-obstruction

First described by Oglivie,[69] acute colonic pseudo-obstruction is occasionally observed among critically ill adults and children who are immobilized in an ICU setting. It is characterized by massive cecal dilation of 5 to 10 cm on abdominal plain film. The mechanism is uncertain, but it appears to occur among patients given neuromuscular blockade and antimotility drugs such as narcotics. If left untreated, it may result in colonic perforation at the cecal level. Therapy should involve decompression of the gastrointestinal tract by nasogastric and rectal intubation and suction. Placing the patient in the prone position also seems to be effective initial therapy. None of these measures, though, seems to be as effective as is parenteral administration of neostigmine.[69] Adverse effects of neostigmine, such as excessive salivation or abdominal cramping, are self-limiting, but bradycardia that occasionally occurs must be managed with atropine.

The critical care physician must be mindful of starting an early and aggressive bowel regimen for patients receiving narcotics, whether as intermittent doses in the awake patient or as continuous infusions in the sedated patient. Use of nonnarcotic analgesics such as intravenous acetaminophen or ketorolac (when appropriate) can help to reduce the incidence of opioid-induced constipation. Furthermore, methylnaltrexone and naloxegol (both opioid antagonists) have now been developed for the treatment of opioid-induced constipation and have used in the pediatric population, although neither has yet been Food and Drug Administration approved in children.[70,71]

Abdominal Compartment Syndrome

Abdominal compartment syndrome (ACS) is defined as organ dysfunction caused by intraabdominal hypertension. The organ dysfunction observed with abdominal compartment syndrome may go underrecognized because it affects patients who are critically ill and their organ dysfunction may erroneously be ascribed to their underlying illness. If untreated, ACS can lead to organ failure and death; timely recognition and intervention can be life saving.

The standard method for measuring intraabdominal pressure is through the assessment of urinary bladder pressure. A three-way stopcock is placed between the catheter and pressure tubing. The bladder is emptied. Sterile isotonic saline is injected in the distal stopcock and into the bladder to allow for a continuous fluid column. There is some variability in the amount of fluid administered based on tubing and patient size. The pressure transducer is zeroed at the level of the midaxillary line, and the pressure is measured at end-expiration while the patient is completely supine. For the most accurate measurement, the patient should also be muscle-relaxed if the clinical scenario allows.

Intraabdominal hypertension (IAH) and ACS are distinct clinical entities. The intraabdominal pressure is a steady pressure within the abdominal cavity. The normal range is variable based on individual patient differences. Much of the variability is due to the body habitus of the patient. IAH is defined as a sustained pressure of 12 mm Hg or greater.[72] ACS is defined as sustained pressure greater than 20 mm Hg associated with organ dysfunction. Although recording of pressure is important for research purposes, the clinical presentation is the most important component in defining ACS. ACS can be classified as primary or secondary. Primary ACS is due to injury or disease in the abdominal region, such as trauma or organ

transplantation, and often requires early surgical decompression. Secondary ACS is due to conditions requiring extensive fluid resuscitation, such as sepsis, burns, or other capillary leak syndromes.

IAH can impair practically every organ system and result in ACS. It can impair cardiac function by reducing venous return as well as impairing cardiac function directly via diaphragmatic pressure. In mechanically ventilated patients, peak inspiratory and mean airway pressures will be significantly increased, resulting in pulmonary barotrauma. In addition, chest wall compliance is markedly reduced. Renal impairment may be attributed to several mechanisms in patients with ACS. Venous drainage can be impaired by renal vein compression. The subsequent cardiac output fall can lead to renal artery vasoconstriction via the renin-angiotensin systems. The urine sodium and chloride concentrations will typically be decreased, whereas the renin, aldosterone, and antidiuretic hormone may be markedly increased.[73,74] The organ most sensitive to changes in intraabdominal pressure is the gut. Both human and animal studies have shown decreased intestinal mucosal perfusion at intraabdominal pressures of 20 mm Hg. Impaired mesenteric venous drainage results in intestinal edema, which can increase intraabdominal pressure and result in worse hypoperfusion and possible bowel ischemia.[75] Finally, intracranial pressure (ICP) can be elevated, leading to a decrease in cerebral perfusion.[76]

The management of IAH and ACS requires both supportive care and, in some instances, surgical decompression. In general, surgical decompression is indicated for ACS. There is increasing evidence that surgical decompression prior to the development of ACS may be beneficial.[77] Following decompression, the abdomen is left open and typically covered with a Dacron mesh or humanized regenerative tissue matrix. Early recognition and timing of decompression of ACS may be crucial in the preservation of organ function (see Chapter 100).

Acute Pancreatitis

Even though gallstone pancreatitis and ethanolic pancreatitis are uncommon in children, numerous structural, toxic metabolic, and infectious diseases are associated with acute childhood pancreatitis. Appropriate radiographic or biochemical evaluation for pancreatitis should be performed on all children admitted to the ICU with acute abdomen.

Acute pancreatitis is preceded by intrapancreatic activation of proteases. The triggering mechanism remains obscure, but once protease inhibitors are overcome and trypsinogen is converted to trypsin, a cascade of steps produces active proteases, lipase, and amylase. The enzymes induce local and distant organ damage, which includes edema, increased vascular permeability, cytolysis, and fat necrosis.

The clinical hallmark of acute pancreatitis is severe, boring epigastric or left upper quadrant pain that radiates through to the back. Serum amylase and lipase levels are greatly elevated, and radiographic imaging studies reveal pancreatic enlargement, sonolucency, or irregularity of the margin. Ultrasonography is a satisfactory screening technique, but CT scanning should be used when the course is severe. If CT scanning is performed with a dynamic, contrast-enhanced technique, interstitial pancreatitis can be differentiated from the more ominous necrotic pancreatitis, which often requires surgical debridement.

Because serum lipase is almost exclusively pancreatic in origin and amylase comes from a number of organs, the serum lipase concentration may be a better indicator of pancreatitis. Use of both measures to follow the course of pancreatitis is preferable to using either one alone.

Several nonspecific laboratory derangements such as anemia, hypoglycemia, hypocalcemia, and hypoproteinemia may occur. Intensive support may be required for severe, acute attacks. Severe, hemorrhagic necrosis of the pancreas carries a poor prognosis. Extraordinarily large third-space fluid and electrolyte losses must be replaced. If significant hyperglycemia occurs, insulin must be given. Calcium infusions may also be necessary. Physicians should be able to minimize pancreatic stimulation by giving the patient nothing by mouth and using nasogastric suction, although the efficacy of suction has been questioned for patients without ileus. Use of protease inhibitors, H_2 antagonists, somatostatin, 5-fluorouracil, and glucagon has not found much support in the literature. Antibiotics are not indicated unless an abscess is suspected. Several complications may be catastrophic. Rupture of a pancreatic duct or leakage of a pseudocyst must be suspected if ascites develops. Gastrointestinal hemorrhage during pancreatitis may originate from a variety of sources. Discovery of gastric varices suggests splenic vein thrombosis. Gastritis may also appear. Pseudoaneurysms of the hepatic or splenic artery may bleed into the pancreas. Small bowel or colonic ischemia caused by fat necrosis may produce gastrointestinal hemorrhage. Infected pancreatic necrosis is uniformly fatal unless the patient undergoes an emergency operation to debride the necrotic tissue.

Time to recovery from pancreatitis is variable and may be prolonged (weeks to months). Early, enteral feeding is the preferred route of nutrition for patients with pancreatitis.[78] Protease inhibitors, free-radical scavengers, and other antiinflammatory agents have all been employed in the treatment of acute pancreatitis, with disappointing results.[79]

Acute and Chronic Liver Failure

The term *liver failure* refers to the constellation of symptoms, signs, and biochemical aberrations that appear when hepatic synthetic capacity is severely compromised. Liver failure is categorized as fulminant when encephalopathy appears within the first 2 months of the illness, as late onset when it appears within 6 months, and as chronic when it appears beyond the sixth month of liver dysfunction. Infectious, metabolic, and toxic liver diseases, as well as biliary obstruction, may lead to liver failure (Table 97.2). Obviously, it is advisable to establish a cause of liver disease before the onset of liver failure. It is beyond the scope of this chapter to outline a diagnostic approach to childhood liver disease, but several reviews are available (see also Chapter 99).[80,81]

TABLE 97.2

Diseases That Cause Liver Failure

Viral	Hepatitis (A, B, C, D, E), CMV, HSV, EBV, VZV, HHV-6, parvovirus B19, parainfluenza, yellow fever
Idiosyncratic	Halogenated hydrocarbons, warfarin, methyldopa, phenytoin, carbamazepine, valproic acid, rifampicin, penicillin, sulfonamides, quinolones
Toxic dose–dependent	Acetaminophen (paracetamol), isoniazid, tetracycline, methotrexate, carbon tetrachloride, amphetamines, *Amanita phalloides* toxin

Toxic synergistic	Ethanol + acetaminophen, barbiturate + acetaminophen, isoniazid + rifampicin
Metabolic	Wilson disease, alpha-1-AT deficiency, galactosemia, tyrosinemia, Reye syndrome, NASH
Associated with pregnancy	Acute fatty liver of pregnancy, HELLP syndrome
Vascular	Budd-Chiari syndrome, veno-occlusive disease, shock, heart failure
Miscellaneous	Autoimmune hepatitis, malignant infiltration, hyperthermia, sepsis

CMV, cytomegalovirus; *EBV*, Epstein-Barr virus; *HELLP*, hemolysis, elevated liver enzymes, and low platelet count; *HHV*, human herpesvirus; *HSV*, herpes simplex virus; *NASH*, nonalcoholic steatohepatitis; *VZV*, varicella zoster virus;

Data from Gotthardt D, et al. Fulminant hepatic failure: etiology and indications for liver transplantation, Nephrol Dialysis Transplant. 2007;22(suppl 8):viii5-viii8.

Elucidating the cause of fulminant hepatic failure is often made more difficult by the rapid development of coagulopathy and ascites, which preclude percutaneous liver biopsy. Laparotomy with surgical wedge biopsy may be necessary. Transjugular liver biopsy is also an option. A core of liver tissue is obtained by passing the biopsy forceps retrograde through the superior vena cava and hepatic vein after introduction via the jugular vein. The biopsy site then bleeds directly into the liver parenchyma, minimizing extravasation.

Hepatic encephalopathy is more difficult to diagnose in young children than in adults, as an infant may first present with simply increased fussiness. Progressive hepatic encephalopathy culminates in coma. When patients have entered coma, central nervous system (CNS) resuscitation becomes necessary. Patients should undergo elective endotracheal intubation; administration of benzodiazepines should be avoided. Beyond CNS metabolic derangements, cytotoxic cerebral edema often complicates hepatic failure. Placement of an intracranial monitoring device should be contemplated; the risk of instrumentation in patients with coagulopathy should be weighed against the benefit of continuous CNS pressure monitoring.[82]

The non-CNS manifestations of liver failure are protean. Hepatosplenomegaly is common in the early stages of fulminant failure, but the liver may shrink rapidly. In end-stage liver disease caused by cirrhosis, the liver is shrunken, firm, and nodular. Most patients with liver failure have jaundice. Spider angiomas, palmar erythema, ascites, and peripheral edema are common features of chronic liver disease. Fetor hepaticus (mercaptan breath) may be present. The biochemical features of liver failure are variable depending on its cause, duration, and severity. Hypoglycemia should be corrected when present. Serum bilirubin levels may be elevated or normal. Liver aminotransferase concentrations are increased in acute liver disease but decrease as hepatocytes are lost and therefore may be only mildly elevated or normal in cirrhosis and in the terminal stages of failure. Decreasing aminotransferase levels and albumin in the face of rising bilirubin, prothrombin time, and partial thromboplastin time denote a failing liver. Serum globulin and ammonia levels are usually elevated. The serum amniogram reveals an elevated aromatic/branched-chain amino acid ratio.

Renal insufficiency may appear because of perennial azotemia, acute tubular necrosis, or hepatorenal syndrome.[83] Patients with both acute and chronic liver failure frequently develop renal failure. Hepatorenal syndrome (HRS) is the most common cause of acute renal failure in this population. From 40% to 80% of patients with hepatic failure develop HRS. The onset often occurs following an acute change in intravascular volume. The development of HRS is precipitated commonly by hemorrhage, excessive diuresis, or sepsis. HRS is a diagnosis of exclusion once other causes of renal failure and absent diuretic response are further explored. Although

certain clinical characteristics may or may not exist in the description of HRS, almost all patients have hyponatremia prior to the development of renal insufficiency.[84] The treatment is nonspecific but includes volume administration and maintenance of adequate systemic perfusion. This is achieved by overcoming the splanchnic vasodilatation and increasing renal perfusion and filtration (see Chapter 75).[85]

Patients with late-onset or chronic liver failure are likely to have portal hypertension. Ascites may develop as plasma oncotic pressure decreases or portal pressure increases. Patients who are hyponatremic usually have total-body sodium overload,[84] and they should be treated with moderate salt restriction, but vigorous fluid restriction, colloid administration, and diuretic therapy are the cornerstones of therapy. High-volume abdominal paracentesis is proved to be safe in both adults and children who have ascites compromising ventilation.

Spontaneous engorgement of esophageal, gastric, and rectal veins leads to varices. Similar prominent veins in the abdominal wall and around the umbilicus (caput medusa) may develop. Splenic congestion from impaired venous flow into the portal system results in splenomegaly and hypersplenism so that patients are classically anemic or pancytopenic. Less commonly, unknown factors lead to intrapulmonary arteriovenous shunting, which characteristically causes hypoxemia.

Coagulopathy and bleeding are frequent in patients with liver failure. Thrombocytopenia, which may be profound, is a common component of hypersplenism. Fat-soluble vitamin malabsorption in patients with cholestasis leads to vitamin K deficiency, which prevents hepatic production of clotting factors II, VII, IX, and X. Ultimately, failed synthesis of all liver-dependent clotting factors results in prolonged prothrombin time (unresponsive to vitamin K administration) and partial thromboplastin time.

The sites of bleeding are predictable. Bleeding from incisions, needle puncture sites, nose, and gingiva are common but are usually not life threatening. Persistent bleeding may require packed red blood cell transfusion. In contrast, intracranial, pulmonary, and variceal bleeding may be fatal and demand immediate attention. Esophageal varices bleed because of acute changes in variceal pressure or because of gastric hyperacidity. Platelets should be given to patients with thrombocytopenia and active bleeding or prior to a procedure. Patients with coagulopathy and hemorrhage may receive fresh frozen plasma, but if not actively bleeding, it is best to allow the international normalized ratio (INR) to rise, as continual replacement of blood product can lead to fluid overload in these already sensitive patients. Acceptable alternatives include plasmapheresis[86] and the administration of recombinant factor VII concentrate[87] as bridges to transplantation (see also Chapter 91).

Mechanical means of hemorrhage control include direct compression, creation of portosystemic shunts, and surgical transection/reanastomosis of the esophagus. Endoscopic control of bleeding from varices involves sclerotherapy in infants too small to tolerate a banding device or endoscopic banding in toddlers and older children.[88] Balloon tamponade by a Sengstaken-Blakemore tube carries substantial risk and has largely been abandoned. It should not be used to manage persistent bleeding after sclerotherapy because of the risk of esophageal perforation.

Complications of portal hypertension can be managed with surgical shunting procedures that decompress the portal system by creating a venous anastomosis between the portal and systemic circulations. Several surgical varieties exist. Central

vascular shunts, such as portocaval or mesocaval shunts, carry substantial risk. Transjugular intrahepatic portosystemic shunts are frequently used in children who weigh more than 10 kg as a bridge to transplantation.[89] In the past, shunt thrombosis was sometimes treated with surgical esophageal transaction, but urgent liver transplantation with either a cadaveric or living related donor is the preferred therapeutic strategy under such conditions (see Chapter 99).

Plasmapheresis or plasma exchange removes circulating mediators and toxins from patients with liver failure. This temporary effect may be due to removal of neuroinhibitory factors. The molecular adsorbent recirculating system (MARS) and other similar albumin dialysis systems, which remove large, albumin-bound molecules such as bilirubin and ammonia, have now been used for several years as a bridge to liver transplantation. These systems have shown an improvement in hepatic encephalopathy and bilirubin with a variable impact on mortality in adults; however pediatric data remain limited.[90] Ultimately, orthotopic transplantation holds the greatest promise for patients with end-stage liver disease.[91]

CHAPTER 98

Applications of Gastrointestinal Pharmacology

Susan Jacob, Silvia M. Hartmann, Ada Kong, Nicole L. Richardson

PEARLS

- Stress ulcer prophylaxis, in the form of a histamine-2 receptor antagonist or proton pump inhibitor, is given to decrease the risk of hemodynamically significant bleeding from the upper gastrointestinal tract.
- Stress ulcer prophylaxis only benefits the patients with risk factors for clinically significant bleeding, such as mechanical ventilation for >48 hours or presence of coagulopathy.
- Despite heterogeneity in the probiotic formulation and dose, overall evidence suggests that probiotic administration prevents antibiotic-associated diarrhea in children.
- Shock and medications are the most important risk factors for constipation in pediatric ICU patients.
- Rectal administration of medication may be most beneficial when intravenous access is challenging or otherwise unnecessary for care.
- Antiemetic management in both chemotherapy-induced nausea and vomiting and postoperative nausea and vomiting is rooted in a multiple-drug approach with distinct targets of action.
- The risk of experiencing chemotherapy-induced nausea and vomiting is mainly determined by chemotherapy-specific factors (eg, emetogenicity of drugs, dose, schedule, route, rate of administration) and can be anticipated.
- Oncology patients who have well-controlled acute nausea and vomiting 24 hours after chemotherapy administration are less likely to have delayed nausea and vomiting. This highlights the importance of prophylactic antiemetic therapy.
- Patients with an operative course greater than 30 minutes are at higher risk of postoperative nausea and vomiting. Tonsillectomy and adenoidectomy are common surgeries associated with postoperative nausea and vomiting.

Stress Ulcer Prophylaxis

The rationale to provide stress ulcer prophylaxis, more commonly called "GI prophylaxis," to children in the PICU is primarily to decrease the risk of hemodynamically significant bleeding from the upper gastrointestinal (GI) tract. This event is generally rare in both adult and pediatric ICU patients. However, when hemodynamically significant bleeding occurs, it is associated with a higher mortality in both pediatrics and adults[1,2] and longer ICU length of stay in the adult population.[1] The risk of universal stress ulcer prophylaxis is of increased infectious complications, most notably ventilator-associated pneumonia (VAP) and *Clostridium difficile* colitis. Restriction of stress ulcer prophylaxis to high risk groups may help to maintain the falling rates of significant upper GI bleeding from stress-related damage while avoiding the infectious complications and excessive cost. There are no cost-effective studies in the pediatric ICU population, but one study from the adult ICU noted that stress ulcer prophylaxis was cost saving if administration could avert 50% of significant bleeding episodes in a population with >15% risk.[3] The same study also concluded that in a low-risk population (<12% risk of significant upper GI hemorrhage) that prophylaxis was not cost effective. Stress ulcer prophylaxis therefore may only be cost saving for high-risk pediatric ICU patients, which are those requiring mechanical ventilation for greater than 48 hours and those with coagulopathy, and must be determined in future studies.

Mechanism of Stress-Related Mucosal Damage

Stress-related mucosal damage is a spectrum of gastric and small bowel injury that varies from asymptomatic superficial mucosal damage to hemorrhagic shock secondary to deeper injury to the intestinal lining and erosion into larger arteries.[4] Stress ulceration that leads to clinically apparent bleeding represents the more severe end of the spectrum of stress-related mucosal damage. Asymptomatic stress-related mucosal damage is likely quite common in high-risk adult ICU populations with one study performed in the 1970s in 32 burn patients showing 74% having multiple areas of gastric mucosal injury within 72 hours of ICU stay.[5] Clinically apparent bleeding has been categorized separately as overt upper GI bleeding and clinically significant upper GI bleeding in most studies. Overt bleeding refers to hematemesis, coffee-ground output from nasogastric or gastrostomy tubes, or melena. Anatomically, overt bleeding is thought to correspond to erosion beyond the mucosa into the submucosa or muscularis propria of the GI tract wall with damage to smaller arteries. This type of bleeding, by definition, does not cause hemodynamic effects. Clinically significant bleeding corresponds to erosion into larger arteries that cause enough blood loss to lead to hypotension or need for blood transfusion.[4,6] Overt bleeding and clinically significant bleeding are the outcome measures of most investigations of stress ulcer prophylaxis described in this chapter.

Stress-related mucosal damage arises from multiple factors commonly found in ICU patients that cause hypoperfusion injury to the GI tract and impair the normal protective mechanisms, which then allows further damage to occur from the multiple corrosive agents produced by the GI system itself.[4,7-9] Hypoperfusion can lead to primary cell damage and predispose to secondary damage from gastric acid and other injurious compounds.[8] Hypoperfusion may be secondary to a low-flow

state or high systemic vascular resistance.[4,9] High intrathoracic pressure from mechanical ventilation may exacerbate low-flow states by further decreasing preload.[4] High systemic vascular resistance in the gastrointestinal tract is a physiologic compensatory mechanism to shunt blood flow to critical organs during times of low effective circulation. Vasoconstriction of the splanchnic circulation also is a consequence of treatment with vasoactive medications common in the treatment of shock. Stress-related mucosal damage may also arise from ischemia-reperfusion injury and the increased production of reactive oxygen species after shock has been reversed.[4] These mechanisms lead to impaired gastric and intestinal protective measures such as decreased mucus, bicarbonate, and prostaglandin production. Gastric acid produced by the stomach, as well as bile and pepsin from duodenal reflux, may all damage the gastric lining when protective mechanisms are impaired. Hypomotility that is often present as a consequence of GI hypoperfusion may exacerbate gastric damage as acidic contents remain in contact with the stomach lining for longer periods of time.[7] Damage is most common in the fundus and upper body of the stomach that are responsible for acid production.[7] Notably, the mechanism for development of stress-related mucosal damage and stress ulceration in critical illness is distinct from variceal bleeding and *H. pylori*–associated ulceration despite similar presentation with upper GI bleeding.

Epidemiology and Risk Factors for Stress Ulceration

Studies from the 1980s showed approximately 25% of the adult ICU population that did *not* receive stress ulcer prophylaxis would have overt upper GI bleeding and 3% to 5% would have clinically significant bleeding.[4] The incidence of overt and clinically significant upper GI bleeding has been decreasing since the 1990s and may be due to earlier reversal of GI hypoperfusion, widespread use of stress ulcer prophylaxis, and perhaps the adoption of early enteral nutrition.[10] Several studies reveal a low incidence of upper GI hemorrhage in both adult and pediatric ICUs. The incidence of clinically significant bleeding among adult ICU patients has been reported to be between 1% and 4.4%.[1,4,10-12] Two prospective pediatric studies performed in the 1990s showed an incidence of overt upper GI bleeding of approximately 6% to 10% and significant bleeding of 0.4% to 1.6%.[2,13] A more recent publication from 2009 examined 110 higher-risk PICU patients who received mechanical ventilation for greater than 48 hours.[14] This study noted a higher rate of upper GI bleeding with 51% of patients having overt bleeding and 3.6% having clinically significant bleeding. This underscores the importance of identifying patients with risk factors for clinically significant bleeding to receive stress ulcer prophylaxis, as the rate of bleeding leading to hypotension or need for transfusion is very low among patients without these risk factors. Cook and associates best demonstrated the significantly different rates of clinically important upper GI bleeding among patients with risk factors to those without.[6] In this study of 2252 adult ICU patients, there were 847 with independent risk factors of coagulopathy or respiratory failure defined as need for mechanical ventilation for greater than 48 hours and 1405 patients with neither risk factor. The incidence of clinically significant upper GI bleeding in those with risk factors was 3.7% compared to 0.1%

in the group without risk factors.

Respiratory failure, coagulopathy, and a pediatric risk of mortality (PRISM) score greater than or equal to 10 was identified as a risk factor for clinically significant GI hemorrhage in children.[2,13] Coagulopathy has been defined as a platelet count less than 100,000/cubic mL, an international normalized ratio (INR) greater than 1.5, or prothrombin time more than twice the control value in many studies. Another study also identified multitrauma (two or more systems involved), a surgical operation longer than 3 hours, and circulatory shock as additional risk factors.[15] One subsequent pediatric study demonstrated mechanical ventilation as the only statistically significant risk factor for significant bleeding after multivariate analysis.[16] A high-risk cohort of children ventilated for greater than 48 hours were at additional risk of GI hemorrhage if organ failure (renal, hepatic, or neurologic) or elevated peak inspiratory pressures >25 cm H_2O were also present.[14] Due to the low incidence of clinically significant hemorrhage, prophylaxis may only be warranted in patients with identified risk factors.

Options for Stress Ulcer Prophylaxis

Histamine-2 (H2) receptor antagonists, proton pump inhibitors (PPIs), sucralfate, and antacids have all been used for prophylaxis of stress-induced mucosal damage in pediatric critical care patients. Classes of medications are described later. A meta-analysis published in 2010 found that treatment with any agent decreased the risk of clinically significant upper GI bleeding with a risk ratio of 0.41 (95% confidence interval [CI] 0.19 to 0.91) in 300 pediatric intensive care unit (PICU) patients from two randomized controlled trials.[17] The same study concluded that no class of medication was superior to prevent clinically significant bleeding based on review of eight randomized controlled trials. However, antacids and sucralfate have fallen out of favor. Both agents require multiple doses per day, lack intravenous formulations, and may chelate or inhibit absorption of other drugs. Sucralfate was compared with ranitidine for stress ulcer prophylaxis in adult ICU patients in a landmark trial by Cook and associates published in 1998.[12] In this multicenter, randomized, and blinded trial, 1200 adult ICU patients who required mechanical ventilation for greater than 48 hours were randomized to nasogastric sucralfate and IV placebo or nasogastric placebo and IV ranitidine. The group receiving ranitidine had a significantly lower rate of clinically significant upper GI bleeding (1.7% versus 3.8%) with a relative risk of 0.44 (95% CI 0.21–0.92). H2 receptor antagonists have been compared to PPIs with contradictory results without a clear medication class that is superior to the other for stress ulcer prophylaxis. A meta-analysis that included seven randomized controlled trials published before 2008 comparing H2 receptor antagonists to PPIs in 936 adult ICU patients found no superiority of either medication to prevent clinically significant bleeding.[18] A subsequent meta-analysis from Cook and associates published in 2013[19] showed that PPIs were superior to H2 receptor antagonists in decreasing the risk of overt and clinically significant upper GI bleeding. The relative risk of developing clinically significant bleeding with PPI therapy compared to H2 receptor antagonists was 0.36 (95% CI 0.19–0.68) using data from 12 trials involving 1614 adult ICU patients. Subsequently, a large retrospective cohort of 35,312 patients had the opposite result.[11] Patients receiving H2 receptor

antagonists had a significantly lower incidence of GI hemorrhage compared to those receiving PPIs (2.1% versus 5.9%, $p < 0.001$). No literature exists in pediatric patients to support the use of either PPIs or H2 receptor antagonists over the other. Interestingly, stress ulcer prophylaxis with medication may only be protective against upper GI bleeding in patients who are not receiving enteral nutrition, which is hypothesized to improve the secretion of protective prostaglandins and mucus. A meta-analysis by Marik and colleagues noted a decreased risk of bleeding in adult ICU patients receiving ranitidine compared to no treatment, but this effect was only present in patients who were not being fed.[10]

Stress ulcer prophylaxis has been recommended as part of routine care for pediatric patients with acute respiratory distress syndrome[20] and sepsis.[21,22] The 2012 Surviving Sepsis Campaign guidelines[22] recommend administration of either an H2 receptor antagonist or a PPI to patients with severe sepsis who also have bleeding risk factors, which include mechanical ventilation for greater than 48 hours, coagulopathy, and hypotension. This was categorized as a strong recommendation with moderate quality evidence (grade 1B). The guidelines suggest the use of a PPI over H2 receptor antagonist, noting poor quality of evidence (grade 2C). It is also suggested that patients without risk factors do not receive stress ulcer prophylaxis. This was a weak recommendation with moderate quality of evidence (grade 2B). The guidelines make no graded recommendations for or against stress ulcer prophylaxis in pediatric patients with severe sepsis or septic shock.

Infectious Complications of Stress Ulcer Prophylaxis

The risk of providing stress ulcer prophylaxis that increases gastric pH to patients in the pediatric ICU is increasing the risk of ventilator-associated pneumonia (VAP) and *Clostridium difficile* infection. The mechanism proposed for higher risk of these infections is that medications that suppress gastric acid production also allow for increased bacterial colonization of the stomach. The higher bacterial load in gastric secretions can be aspirated around the endotracheal tube leading to ventilator-associated tracheitis or VAP. Similarly, *C. difficile* spores remain increasingly viable in a less acidic gastric environment with increased risk of causing colitis.

More recent adult studies of stress ulcer prophylaxis in the ICU have called into question the higher risk of VAP with acid suppression.[10,19] One study suggested a higher rate of VAP with PPIs compared to H2 receptor antagonists, but conclusions are limited by the retrospective design in which the population receiving PPIs may not be the same as the population receiving H2 receptor antagonists.[11] Studies from the pediatric ICU have not shown a difference in VAP rates between patients receiving prophylaxis with sucralfate versus ranitidine versus no prophylaxis.[23,24]

The association between acid suppression and *C. difficile* has been demonstrated mainly in adults in both the outpatient and hospitalized setting use case-control studies that also take into account antibiotic use.[25] More recently studies with a similar design have shown the same relationships of increased *C. difficile* infection in patients who have received either PPIs or H2 receptor antagonists.[26,27] These studies have captured both outpatient and hospitalized pediatric patients, but no study has specifically focused on the ICU population receiving acid suppression for stress ulcer

prophylaxis.

Histamine-2 Receptor Antagonists

Histamine-2 (H2) receptor antagonists inhibit gastric acid secretion by means of competitive inhibition of H2 receptors of the gastric parietal cells. H2 receptor antagonists are commonly used because of the availability of both enteral and intravenous formulations. Common adverse effects include nausea and headache. Tachyphylaxis is well documented for intravenous and oral H2 receptor blockers in adult and pediatric populations. Although thrombocytopenia may occur, it is often difficult to determine the sole cause in critically ill patients. Ranitidine should be avoided in patients with acute porphyria. All of the currently available H2 receptor blockers require a dosage adjustment for renal impairment and have a higher risk of central nervous adverse effects without dose adjustment.

Proton Pump Inhibitors

By covalently bonding to the hydrogen-potassium-adenosine triphosphatase (H^+-K^+ ATPase or proton pump) of parietal cells, proton pump inhibitors (PPIs) suppress gastric acid secretion for the life of the parietal cell. PPIs may be used orally, intravenously, or off-label through feeding tubes. Ideally, enteral therapy should be given 30 minutes before feeding so that peak plasma concentrations coincide with parietal cell stimulation. Administration of enteral PPIs with food reduces bioavailability by 50%. Omeprazole, esomeprazole, and lansoprazole have been approved for use in pediatrics. Intravenous lansoprazole is no longer available. Neither intravenous pantoprazole nor esomeprazole is Food and Drug Administration (FDA)–approved for use in pediatric patients. Although PPIs are generally thought of as well tolerated, both long- and short-term adverse effects are gaining more attention. Reactions include idiosyncratic reactions, drug-drug interactions, drug-induced hypergastrinemia, and drug-induced hypochlorhydria.[28] The most common side effects are headache, diarrhea, constipation, and nausea. PPIs should not be discontinued abruptly because a hypersecretory phase results.[28,29]

Sucralfate

Sucralfate is an aluminum salt of sulfated sucrose. Safety concerns about sucralfate have been associated with aluminum toxicity[29] and interference with medication absorption or medication chelation. Sucralfate requires administration into the stomach to be effective, thus nasoduodenal and jejunostomy tube dependence limits the utility of this medication for stress ulcer prophylaxis.

Gastrointestinal Hemorrhage

Clinical guidelines for treatment of nonvariceal upper GI bleeding in adults include recommendations for pharmacotherapy.[30] Unfortunately, this body of evidence does not exist in the pediatric population. H2 receptor antagonist use is discouraged as primary treatment for patients with acute bleeding. Although octreotide and

somatostatin are more effective than H2 receptor antagonists, these agents are also not recommended for routine management. PPIs are cited as the drugs of choice for treatment of acute nonvariceal upper GI bleeding.[30] High-dose intravenous proton pump inhibitor therapy (80 mg pantoprazole bolus followed by 8 mg/hr for 72 hours) after endoscopic therapy is preferred over H2 receptor antagonists alone, or in combination with octreotide, to prevent rebleeding in adult patients. As more data become available regarding the use of intravenous proton pump inhibitors in pediatric patients, parallels may be seen between the treatments of adult and pediatric nonvariceal upper GI bleeding.

High-Dose Proton Pump Inhibitors

Choices for high-dose intravenous PPIs to treat GI hemorrhage include pantoprazole and esomeprazole. Neither product's intravenous formulation has been well studied in children. Doses for children have been extrapolated from the adult high-dose intravenous pantoprazole recommendations for nonvariceal upper GI bleeding.[31] Although it is not yet specified in the literature, many pediatric sites reportedly use a pantoprazole loading dose of 2 mg/kg IV, followed by 0.2 mg/kg/hr for 72 hours (neither the loading dose nor continuous infusion should exceed the adult dose).

Octreotide and Somatostatin

Octreotide is a somatostatin analogue. Its pharmacologic actions include inhibition of gastric acid secretion and decreased splanchnic blood flow. Although its 1.7-hour half-life is approximately 30 times longer than that of somatostatin, octreotide is usually administered through continuous infusion for GI hemorrhage. Adverse effects include abdominal pain, sinus bradycardia, nausea and vomiting, pain at the site of injection, elevation of liver enzymes, hyperglycemia, chest pain, headache, dizziness, fatigue, flushing, and diarrhea. Long-term use (longer than 1 month) has been associated with changes in thyroid function, gallstone formation, and cholecystitis.[32]

In adults, octreotide has been shown to decrease the duration of hemorrhage and prevent recurrence of peptic disease more so than cimetidine or ranitidine. A Cochrane review cited improved initial hemostasis and decreased transfusion requirements; however, no change was evident in rebleeding or secondary outcomes when octreotide was used to treat variceal bleeding.[32] Few researchers have evaluated octreotide for GI hemorrhage in children. In one study, continuous infusion of octreotide in seven patients was evaluated. Bleeding ceased in six of the seven patients. The duration of infusion ranged from 24 to 234 hours. Although bleeding stopped within 24 hours in nearly half of the patients, on average, bleeding stopped after 40 hours. The most notable adverse effect was hyperglycemia.[33] Subcutaneous octreotide has also been used for severe chronic GI hemorrhage for extended periods of 24 to 50 months.[34]

Vasopressin

Vasopressin has been used for treatment of variceal bleeding more frequently than for nonvariceal upper GI bleeding. In fact, adult guidelines do not address the use of

vasopressin for nonvariceal bleeding. Vasopressin acts by mechanisms similar to octreotide; however, its hypertensive effects on blood pressure make it a less desirable option in many patients.[35] From a medication safety perspective, vasopressin prescribing can be confusing given the wide range of accepted dosing conventions and variety of indications in pediatric patients (eg, diabetes insipidus, GI hemorrhage, shock). Dosing recommendations that require units per kg per unit time require careful decimal place checks. Intensive care units should decide on the accepted dosing convention and dose range for vasopressin for each indication and use infusion pumps with safety software that can accommodate the predetermined limits to prevent 10-fold dosing errors.

Antibiotic-Associated Diarrhea

Diarrhea occurs commonly in the pediatric ICU where patients are also at elevated risk of antibiotic-associated diarrhea and *Clostridium difficile* colitis because many are receiving antibiotics empirically or for identified infection. Diarrhea in critically ill patients is estimated to occur in 14% to 21% of the population, with the median onset of symptoms occurring 6 days after ICU admission.[36]

Antibiotic treatment may lead to disturbance in the normal microbiota of the gut, resulting in a range of symptoms, notably diarrhea. Diarrhea has been reported in up to 40% of children receiving broad-spectrum antibiotics; antibiotics with activity against anaerobes such as aminopenicillins, cephalosporins, and clindamycin are most commonly implicated.[37] Treatment of antibiotic-associated diarrhea has centered around replacing gut flora using probiotics. Probiotics are nonpathogenic viable microorganisms (bacteria or yeast), which when administered in sufficient amounts provide a health benefit to the host.[38] Probiotic use has steadily gained popularity and acceptance. Commonly available bacterial probiotics in the United States include various species of *Lactobacillus, Bifidobacterium, Streptococcus, Lactococcus lactis,* select *E. coli,* and some *Enterococcus* species.[39] The only probiotic yeast available is the nonpathogenic *Saccharomyces boulardii*. Currently there exists huge variability in the published data with regard to probiotic strain, dose, and duration of therapy for antibiotic-associated diarrhea (AAD). However despite this heterogeneity, a Cochrane[37] review concluded that the overall evidence suggests a beneficial effect of probiotics in the prevention of pediatric AAD. Most common adverse effects reported are abdominal cramping, nausea, fever, soft stools, and flatulence.[38] Although probiotics are generally well tolerated, their use has been linked to serious adverse events such as bacteremia and fungemia.[38,39] Risk factors for these rare side effects include immunosuppression, infant prematurity, short gut syndrome, insertion of central venous catheter, prosthetic heart valves, and the presence of a jejunostomy tube.[38,39]

Clostridium Difficile–Associated Diarrhea

C. difficile is the most frequently reported nosocomial pathogen in the United States. It is an anaerobic, gram-positive bacterium that is transmitted via the fecal-oral route. *C. difficile* releases two toxins, toxins A and B, which are associated with intestinal secretion, inflammation, and monocyte cytokine release leading to diarrhea. The B1/NAP1/027 strain of *C. difficile* is relatively new and is associated

with more severe *Clostridium difficile*–associated diarrhea (CDAD) and is often seen in hospital-acquired CDAD. *C. difficile* infection is diagnosed by testing for toxins in stool by enzyme immunoassay or by polymerase chain reaction testing.[40,41]

The most important risk factor for *C. difficile* infection is antibiotic use. Pediatric ICU patients represent a high-risk group for *C. difficile* infection, as they commonly receive empiric antibiotics. Almost all antibiotics have been associated with infection, but the most frequently reported offenders are ampicillin, amoxicillin, cephalosporins, clindamycin, and flouroquinolones.[40] Other established risk factors include increasing age in adults, concurrent use of proton pump inhibitors, immune deficiency, malignancy, and inflammatory bowel disease.[40,41] In addition to antibiotic stewardship, hand washing and patient isolation are the cornerstones for prevention of the spread of CDAD in health care facilities.[40,41]

For many decades, the mainstays for the treatment of *C. difficile* have been with metronidazole or vancomycin for 10 to 14 days. More recent data have shown the superiority of vancomycin in patients with mild, moderate, and severe disease.[40,41] The decreasing cost of vancomycin along with a favorable side effect profile compared to metronidazole has led to its increasing use.

Fidaxomicin is a new macrocyclic antibiotic with proven bactericidal activity against *C. difficile*; it is poorly absorbed from the GI tract. In clinical trials, the cure rate for acute infection was comparable between fidaxomicin and vancomycin; however, the recurrence rate was 15% among patients on fidaxomicin compared to 25% recurrence on vancomycin.[40] Fidaxomicin is FDA approved for the treatment of *C. difficile* in adults over 18 years old. Currently there are no data on pediatric dosing.

Constipation

Although there is no consensus on the definition of pediatric constipation in the intensive care unit, nor has it been extensively studied, the incidence is thought to be 33% to 50%.[42] Constipation is the result of altered motility of the colon and rectum. Constipation occurs commonly in patients receiving opioid medications to tolerate mechanical ventilation or for postoperative pain.

Shock and medications such as sedatives are the most important risk factors for constipation in the ICU.[43] Other contributing factors include severity of illness, immobilization, dehydration, or an inadequate diet. In shock states, splanchnic perfusion is severely reduced, altering tolerance to enteral nutrition, and can cause structural changes in the gastrointestinal tract.[43] The differential diagnosis of constipation in a pediatric intensive care unit is extensive and includes anatomic, metabolic, neurologic, and connective tissue disorder.[44,45] Chronic constipation in a patient in the ICU may merit investigation of the underlying cause. Medications such as opiates, phenobarbital, antacids, antihypertensives, and anticholinergics can all contribute to a child's constipation.[44,45]

Prevention and Treatment

In the ICU, prevention should be considered in certain populations where constipation is particularly common, could have serious negative outcomes, or where straining may be problematic for the operative site. Some pediatric ICUs have

incorporated a bowel regimen as part of enteral nutrition protocols given the frequency of constipation.[46] Prevention usually includes a combination of agents to maintain bowel function.[45]

When considering treatment, any underlying disease state or anatomic anomaly should be managed individually. If medication related, the offending agent should be discontinued if possible. Constipation itself is addressed as a two-step process of disimpaction lasting 3 to 5 days, followed by maintenance therapy (Table 98.1).[47,48]

TABLE 98.1

Medications for Treatment of Constipation

Drug Class		Formulations	Adverse Effects/Contraindications
Osmotic			
	Lactulose	Oral solution	Flatulence, abdominal cramps, hypernatremia when used in high doses
	Sorbitol	Oral and rectal solution	
	Barley malt extract		
	Magnesium citrate	Liquid	Hypermagnesemia, hypophosphatemia, and secondary hypocalcemia; infants are at an increased risk of hypermagnesemia
	Magnesium hydroxide (milk of magnesia)	Oral suspension or chewable tablet	
	PEG 3350 (MiraLax)	Powder for oral suspension	
Osmotic Enema			
	Phosphate enemas	Rectal enema	Avoid in children <2 years old; rectal wall injury, abdominal distention, vomiting, severe hyperphosphatemia, severe hypocalcemia, tetany
Lavage (continuous infusion via nasogastric tube)			
	Polyethylene glycol-electrolyte solution (Golytely)	Powder for suspension	Nausea or vomiting, bloating, abdominal cramps, hyperphosphatemia, anal irritation, aspiration pneumonitis/pulmonary edema
Lubricant			
	Mineral oil	Oral liquid and rectal enema	Not recommended for <1 year old. Nausea or vomiting, abdominal discomfort, may decrease fat-soluble vitamins, lipoid pneumonia if aspirated
Stimulants			Abdominal pain, cathartic colon (possibility of permanent gut, nerve, or muscle damage)
	Senna	Oral syrup and tablets; chewable tablets	Nausea or vomiting, diarrhea, discoloration of urine; idiosyncratic hepatitis, melanosis coli; hypertrophic osteoarthropathy, analgesic nephropathy
	Bisacodyl	Delayed release tablets, rectal enema and suppositories	Abdominal pain, diarrhea, hypokalemia, abnormal rectal mucosa, and (rarely) proctitis
	Glycerin suppositories	Adult and pediatric rectal suppositories	Nausea or vomiting, diarrhea, rectal irritation

Adapted from Baker SS, Liptak GS, Colletti RB, et al. Clinical practice guideline: evaluation and treatment of constipation in infants and children: recommendations of the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition. J Pediatr Gastroenterol Nutr. 2006;43:e1-13.

Disimpaction may be accomplished with oral or rectal medication administration. The oral route is less invasive and may give a sense of empowerment to the child, but the rectal route is quicker and may be necessary if the child has abdominal pain.[47]

Recommended daily maintenance therapy includes mineral oil (a lubricant) or magnesium hydroxide, lactulose, sorbitol, polyethylene glycol (PEG) (osmotic laxatives), or a combination of lubricant and laxative. The prolonged use of stimulant laxatives is not recommended in children. The preferred, acceptable palatability and superior osmotic agent in children is PEG 3350.[49] Although

preliminary, clinical data suggest that the administration of PEG 3350 to infants is effective without any adverse effects noted.[50] Intermittent, short-term use of a stimulant laxative may be necessary to avoid recurrence of an impaction, but it should be avoided for extended use.[47]

Long-term follow-up studies have demonstrated that a significant number of children continue to require therapy to maintain regular bowel movements.[47,50]

Rectal Administration of Medication

Many drugs otherwise approved for oral or intravenous use have been administered rectally in both adults and children. The rationale for using the rectal route depends on the patient's clinical status. Rectal administration allows for avoidance of the orogastric route when the intravenous route is not an option or when parenteral dosage forms are not available. The rectal route allows for a higher local concentration of drug in situations where limited systemic absorption is desired. Although generally well accepted among patients and their families,[51,52] clinicians may need to overcome resistance to rectal administration from patients and families because of personal perceptions.

Interpatient variability surrounding rectal administration and the pharmaceutical formulation are key factors for clinicians to consider.[53] The result of these issues is that drug absorption may be accelerated or delayed. First, the formulation of the product itself varies, causing differences in the time to liquefaction with suppositories, the volume of liquid administered, and the concentration of the drug. Drugs administered high in the rectum, which is drained by the superior rectal veins, typically are carried to the liver via the portal vein, thus they are subject to first-pass hepatic metabolism. Drugs administered low in the rectum are delivered into the venous circulation by the inferior and middle rectal veins before passing through the liver. The presence of stool in the rectum and rectal pH can alter drug absorption. Rectal pH affects absorption by ionizing varying amounts of drug. The rectal mucosa in children typically has a more alkaline pH.[54] Nonionized drugs have greater lipid solubility, causing enhanced absorption across biological membranes. The rectal retention of the drug administered also affects absorption.[55]

The rectal route has been commonly studied with the use of rectal diazepam gel (Diastat). This commercially available product is used for prolonged or repetitive seizures in children and has approval by the FDA for at-home administration by a trained nonprofessional caregiver. Clinical trials and postmarketing data have reported a low rate of serious respiratory adverse events.[56,57] Rectal administration offers an alternative to other oral and intravenous benzodiazepine options available in a critical care setting, especially in emergent situations if access cannot be readily achieved.[55,56] Several orally available medications have been administered rectally including anticonvulsants such as diazepam, lamotrigine, levetiracetam, phenobarbital, topiramate, valproate, and carbamazepine for status epilepticus[57,58]; sedatives such as diazepam, midazolam, and ketamine in varying uses[55,59]; localized treatment for irritable bowel disease using mesalamine[60-62]; vancomycin for pseudomembranous colitis[62a]; antibacterial agents such as erythromycin and azithromycin[63]; antiemetics[64]; cardiovascular agents such as nifedipine and metoprolol[65-68]; and analgesics, specifically acetaminophen, nonsteroidal antiinflammatory drugs (ibuprofen), and tramadol, for temperature reduction and

postoperative pain control.[51,52,69,70] Although the American Academy of Pediatrics dissuades the rectal use of acetaminophen without consultation with a health care provider,[71] it has been widely used and studied.[69,70,72,73] In addition, rectally administered nonsteroidal antiinflammatory medications, opioid analgesics, antiseizure medications, antiemetics, anticholinergic medications, antidepressants, psychostimulants, and antibiotics have been used with success in the hospice and palliative care settings.[74]

In a pediatric critical care environment, rectal administration of medication may be most beneficial when intravenous access issues are present, either because of an inability to maintain or achieve intravenous access or in situations when placement of an intravenous line is otherwise not necessary. Rectal administration in children is relatively painless and comparable to rectal temperature monitoring, a common practice. Practical considerations for prescribers include knowledge of available dosage forms for rectal use, interpatient variability of absorption, varying amounts of immeasurable drug expelled by the patient (thus altering dosage), and social considerations including patient or family perceptions of rectal medications, especially in older children and adolescents.

Nausea and Vomiting

Introduction and Definitions

Uncontrolled nausea and vomiting in the pediatric intensive care unit may result in consequences that range from minor patient discomfort to electrolyte imbalance or surgical site complications. To the patient this can mean wound dehiscence, GI bleeding, malnutrition, dehydration, pulmonary aspiration, and increased anxiety with future medical interventions.[75]

Two populations seen in the PICU that commonly experience nausea and vomiting are oncology patients after chemotherapy administration and postoperative admissions. Indeed, nausea and vomiting have been referred to as the "big little problem" with the capacity to delay discharge, monopolize nursing care, and impact financial resources.[76] These costs can be limited with a focus on prophylactic treatment, employing recent drug developments and guideline-driven therapy when possible. The data that drive these guidelines are, particularly in pediatrics, largely based on studies that look at vomiting more specifically than nausea.[77] Because nausea is an unpleasant sensation in the epigastrium, it is more difficult to quantify objectively compared to vomiting.[77,78] Nausea may be associated with flushing, tachycardia, and an urge to vomit. Vomiting, defined as the forceful expulsion of gastric contents from the mouth, can be more easily measured for medication assessment purposes. Unless otherwise noted, when management of vomiting is discussed here, it can be inferred to also pertain to managing nausea (unless otherwise noted). Retching (also known as dry heaving) is defined as gastric and esophageal contractions without expulsion of vomitus.

The causes of nausea and vomiting in intensive care are diverse, including radiation, intracranial hypertension, meningitis, diabetic ketoacidosis, hypercalcemia, hyponatremia, hepatitis, pancreatitis, bowel obstruction, GI bleeding, postoperative ileus, and medication administration. Common medications that can trigger vomiting include antineoplastics, anesthetics, antibiotics, contrast media, and

opiates. The majority of research has focused on chemotherapy-induced nausea and vomiting (CINV) and postoperative nausea and vomiting (PONV). Before moving on to these topics specifically, the mechanism mediating nausea and vomiting will be explored.

Pathophysiology of Emesis

The vomiting center or emetic center or *central pattern generator*, located in the medulla oblongata, is a collection of neurons that may trigger vomiting after receiving input from the chemoreceptor trigger zone, abdominal vagal afferents, or cerebral cortex.[75,79-81] The chemoreceptor trigger zone, located in the area postrema region near the fourth ventricle, is not fully protected by the blood-brain barrier and is therefore vulnerable to antineoplastic agents or other stimuli in the blood or cerebral spinal fluid.[79-81] The vagus nerve provides important stimuli to both the chemoreceptor trigger zone and vomiting center, and it appears to have the largest role in CINV.[79,81] This occurs when cells within the GI tract are exposed to chemotherapy and release mediators, including 5-hydroxytryptamine (5-HT), substance P, and cholecystokinin, that stimulate the vagus nerve.[79,81] Finally, the role of the cerebral cortex is less well defined but is thought to play a role in anticipatory nausea and vomiting.[75]

The mechanism described is most dependent on the neurotransmitter receptors for dopamine, serotonin (5-hydroxytryptamine type 3 or 5-HT3), and substance P.[75,79-81] Additional receptors that are thought to play a supporting role include corticosteroid, histamine, cannabinoid, acetylcholine, opiate, neurokinin-1, and gamma-aminobutyric acid (GABA).[75,80,82] The intricate cascade briefly described here and multiple neurotransmitter involvement foreshadow treatment guidelines that will often be rooted in multiple agents that target various pathways.

Chemotherapy-Induced Nausea and Vomiting

Emesis that occurs from chemotherapy is divided into four categories. Anticipatory CINV occurs prior to chemotherapy administration (hours to days) and occurs as a conditioned response in patients that have had significant past CINV. Acute CINV occurs within 24 hours following chemotherapy administration and is the most widely studied. Delayed CINV occurs more than 24 hours after and usually occurs within 7 days of chemotherapy administration. Breakthrough (or refractory) nausea and vomiting occur during any phase despite antiemetic prophylaxis or treatment. The risk of experiencing nausea and vomiting is mainly determined by chemotherapy-specific factors (eg, emetogenicity of drugs, dose, schedule, route, rate of administration). Pediatric patients that have well-controlled acute nausea and vomiting are less likely to have delayed nausea and vomiting.[82] This highlights the importance of staying ahead of symptoms with prophylactic treatment.

5-HT3 Receptor Antagonists

The advent of 5-HT3 receptor antagonists in the early 1990s provided a new cornerstone in how acute nausea and vomiting are managed in patients receiving highly or moderately emetogenic chemotherapy. The first-generation 5-HT3 receptor

antagonists of dolasetron (Anzemet), granisetron (Kytril), and ondansetron (Zofran) have been established in pediatrics to be equally effective, and the most common adverse effects include headache, constipation, fatigue, and dizziness.[77,83-87] It should be noted that the approved pediatric dose of granisetron of 10 μg/kg once daily is likely ineffective, and a dose of 40 μg/kg once daily is more appropriate.[77,87,88] The IV formulation of dolasetron is contraindicated for CINV due to a dose-dependent increase in QT prolongation and risk of developing torsades de pointes.[89] In adults, the 5-HT3 receptor antagonists have been established, at the appropriate doses, to be as effective when given orally as when given intravenously and that single daily dose schedules are as effective as multiple-dose schedules.[88,90-94] However, there are limited data regarding the selection of appropriate dosage form for pediatric patients.[95] These agents are most useful for CINV occurring within the first 24 hours after administration of chemotherapy.[96]

A second-generation 5-HT3 receptor antagonist, palonosetron (Aloxi) gained Food and Drug Administration approval for both acute and delayed CINV in 2003. It is unique from other 5-HT3 antagonists because of its long half-life (21 to 37 hours in children and 40 hours in adults) and greater affinity for 5-HT3 receptors.[97] All 5-HT3 receptor antagonists except palonosetron affect the QT interval. Three phase III trials have established that palonosetron is not inferior to older 5-HT3 antagonists.[98-101] Further prospective study is needed before palonosetron can be established as superior to other 5-HT3 receptor antagonists. To date, CINV guidelines have not stated any one 5-HT3 receptor antagonist to be superior to another.[88] Higher weight-based doses of 5-HT3 antagonists may be required in children due to variation in pharmacokinetics as compared to adults.[88]

Corticosteroids

Corticosteroids, most commonly dexamethasone or methylprednisolone, are potent antiemetics and have a critical role in managing acute and delayed CINV in pediatrics. Their exact mechanism of action is unclear but may involve decreasing 5-HT3 release in the peripheral nervous system.[102] Addition of a corticosteroid with a 5-HT3 receptor antagonist is considered the standard of care for patients receiving moderate or highly emetogenic chemotherapy. However, corticosteroids also have the potential to decrease the effect of antineoplastic drugs on brain tumors, osteosarcomas, and carcinomas.[102] Dexamethasone may increase the resistance of certain tumors to both radiation and chemotherapy.[77] Interferon or interleukin-2 may be less effective when used along with steroids.[75] Corticosteroids may also impact the quality of brain tumor images generated by computed tomography or magnetic resonance imaging by altering the distribution of contrast media.[77] In addition to these concerns, the usual side effects of steroids must be kept in mind, including gastritis, hyperglycemia, hypokalemia, anxiety, euphoria, and insomnia. If corticosteroids are contraindicated, then chlorpromazine, metoclopramide, or nabilone may be used instead.[103] It would be prudent to consult a patient's chemotherapy protocol or an oncologist before initiating corticosteroids in a pediatric patient with a malignancy to verify the appropriateness of this approach.

Substance P/Neurokinin-1 Receptor Antagonists

The substance P/neurokinin-1 receptor antagonist is the most recent antiemetic class.

These substances are effective for both acute and delayed nausea and vomiting in moderately and highly emetogenic chemotherapy. They are currently approved in adults for prevention of CINV when used in conjunction with a 5-HT3 antagonist and a corticosteroid in moderate or highly emetogenic chemotherapy regimens. Currently the medications that represent this class on the market are oral aprepitant and intravenous fosaprepitant (prodrug of aprepitant). A fixed combination of oral palonosetron and netupitant (Akynzeo) was approved in 2014. This class of drug is generally well tolerated with diarrhea, fatigue, headache, and hiccups being common side effects.[104-106] Both aprepitant and fosaprepitant are substrates, inhibitors, and inducers of the cytochrome P-450 enzymes 3A4 and 2C9. A thorough review of potential interactions for individual patients is merited (most notably warfarin, oral contraceptives, and chemotherapy agents). Concomitant corticosteroid dose should be decreased by 25% if given IV and by 50% if given PO.[107] Although none are currently approved for children, there have been several single-center case studies documenting the use of aprepitant and fosaprepitant in children and adolescents.[108-110] One study examined aprepitant dosed for young adults in patients ages 11 to 19 years weighing 43 to 105 kg.[111] Aprepitant-containing regimens performed comparably to non–aprepitant-containing regimens, but an increase in the number of cases of febrile neutropenia was noted in the aprepitant patients.[111] A single-center, prospective, observational study evaluated the safety and efficacy of aprepitant in patients between age 1 and 17 years (mean age 9.55 + 4.85) using a weight-based dosing table. Through patient survey, incidence of nausea, emesis episodes, inference with activities of daily living, and appetite were evaluated. Eleven patients were enrolled. Aprepitant was well tolerated, and the complete response (defined as no nausea, vomiting, or use of rescue therapy) rate was 38.9%.[108] Until further pediatric experience is established, routine use of aprepitant should be reserved for children age 12 and older who are receiving highly emetogenic chemotherapy.

Other Antiemetic Agents

Several other agents are used in pediatrics for CINV. Lorazepam is routinely employed for anticipatory nausea and vomiting (up to a maximum dose of 2 mg) given once at bedtime the night before chemotherapy and once the next day prior to chemotherapy.[112] Diphenhydramine is anecdotally used in pediatric patients, despite its absence from guidelines and reviews of CINV.[77,88] Dopamine receptor antagonists, including phenothiazines (eg, prochlorperazine), butyrophenones (eg, droperidol), and benzamides (eg, metoclopramide), cause a high incidence of dystonic reactions when used at high doses for several days and potentially oculogyric crisis.[88,113] Cannabinoids (ie, dronabinol) are limited by their lack of pediatric data and their side effects, which include euphoria, sedation, depression, and hallucinations.[114] A scopolamine patch may have some utility in patients older than 12 years that are able to wait up to 12 hours for relief.[77] Olanzapine is an atypical antipsychotic medication that has shown efficacy for treatment of CINV in adults. A retrospective, multicenter review of olanzapine use in children for CINV suggests that this medication could potentially be an important antiemetic option; however, further research is warranted.[115] Generally speaking, these agents should only be considered for pediatric patients who do not tolerate first-line therapy alone.

Treatment Guidelines for Chemotherapy-Induced Nausea and Vomiting

Determining appropriate antiemetic therapy requires one to first evaluate the likelihood that a particular chemotherapy regimen will produce nausea or vomiting.[88,116,117,95] This has been accomplished with literature and expert opinion and is summarized in Table 98.2. This categorization is largely based on adult data, so it is vital to take individual patient parameters and CINV history into account. If a chemotherapy regimen is close to the next highest emetic risk category, it is better to be aggressive with antiemetic management. Typically, combination chemotherapy is more emetogenic than single-agent chemotherapy. Choice of antiemetic(s) should be individualized based on the emetogenicity of chemotherapy given, tolerance to previous cycles, potential anticipatory nausea or vomiting, concomitant medications, or history of adverse events or allergic reactions.[118] In general, a first-generation 5-HT3 receptor antagonist plus dexamethasone is recommended for children receiving moderate or highly emetogenic chemotherapy. Dosing should be administered scheduled and not as needed. The initial dose prior to initial chemotherapy should be given 30 minutes if IV or 1 hour if PO.[118]

TABLE 98.2

Emetogenicity of Frequently Encountered Pediatric Chemotherapy

Emetic Risk (Incidence of Emesis With No Prophylaxis)	Antineoplastic Agent[a]
High (>90%)	Carboplatin Carmustine >250 mg/m^2 Cisplatin Cyclophosphamide >1.5 g/m^2 Cytarabine 3 g/m^2/dose Dactinomycin Methotrexate >12 g/m^2 Procarbazine (oral) Streptozocin Thiotepa >300 mg/m^2
Moderate (30%-90%)	Carmustine <250 mg/m^2 Cyclophosphamide <1 g/m^2 or oral Cytarabine >1 g/m^2 Daunorubicin Doxorubicin Etoposide (oral) Ifosfamide Intrathecal therapy (methotrexate, hydrocortisone, cytarabine) Irinotecan
Low (10%-30%)	5-Fluorouracil Busulfan (oral) Cytarabine <200 mg/m^2 Docetaxel Doxorubicin (liposomal) Etoposide Methotrexate >50 to <250 mg/m^2 mg/m^2 Paclitaxel Topotecan Vorinostat
Minimal (<10%)	6-Thioguanine (oral) Asparaginase (IM or IV) Bevacizumab Dasatinib Erlotinib Fludarabine Hydroxyurea (oral)

	Mercaptopurine (oral) Methotrexate <50 mg/m^2 or oral Rituximab Sorafenib Sunitinib Temsirolimus Vinblastine Vincristine

[a]Table focuses on more common pediatric chemotherapy and is not exhaustive. Medication is parental unless otherwise stated.

Modified from Dupuis LL, Boodhan S, Holdsworth M, et al. Guideline for the prevention of acute nausea and vomiting due to antineoplastic medication in pediatric cancer patients. Pediatr Blood Cancer. 2013;60:1073-1083.

Medications that are less well supported for delayed CINV, such as diphenhydramine or 5HT3 receptor antagonists, may be employed based on individual practitioner preference. Other areas of future research include breakthrough emesis that occurs despite adequate prophylaxis in a single chemotherapy cycle and refractory emesis that occurs despite adequate prophylaxis over multiple chemotherapy cycles.[82] Additional areas that require further investigation in pediatric CINV include multiple-day chemotherapy, high-dose chemotherapy with stem cell rescue, and intractable symptoms in terminal patients.[119-121] Finally, each institution would be well advised to conduct a pharmacoeconomic review to aid in antiemetic selection of pharmacologically equivalent products.

Postoperative Nausea and Vomiting

Postoperative nausea and vomiting (PONV) is one of the most common complications in pediatric surgery. The rate of PONV in children can be twice that in adults (between 33.2% and 82%), thereby emphasizing the importance of prophylaxis.[122,123] The etiology of PONV is multifactorial with risk factors mainly related to the surgical procedure, the patient, and the type of anesthesia. Strabismus repair, ear-nose-throat (tonsillectomy and adenoidectomy), appendectomy, hernia and orchidopexy surgery, or any procedure where anesthesia time is 30 minutes or longer has an increased likelihood of PONV.[78,122-124] Children aged 3 years and older continue to increase their risk of PONV until they become pubescent.[122,124] Patients who have a history of PONV, motion sickness, or patients with first-degree relatives with such histories are more prone to have PONV.[122,124]

In a single-center, prospective study of pediatric anesthesia, Eberhart and colleagues identified four independent risk factors: strabismus repair, duration of surgery >30 minutes, age >3 years, and previous history of PONV in patient or relatives. The presence of 0, 1, 2, 3, and 4 risk factors predicts the risk of PONV as approximately 9%, 10%, 30%, 55%, or 70%, respectively.[109]

Prophylaxis is recommended only for children thought to be at moderate or high risk of PONV.[78] Regional anesthesia is optimal in such patients.[78] However, if general anesthesia is necessary, the following may reduce the baseline risk of PONV: use of regional anesthesia versus general anesthesia, adequate hydration, use of propofol infusions, and avoiding nitrous oxide or volatile anesthetics and minimizing opioids when possible.[110,122]

Patients at moderate or high risk should receive prophylaxis therapy with a combination of at least two agents with distinct mechanisms of action.[78,122] A 5-HT3

receptor antagonist and dexamethasone combination is recommended as first choice and is preferable to single agents.[122] Other options for prophylaxis include dimenhydrinate, droperidol, and perphenazine. Neurokinin 1 (NK-1) receptor antagonists have been established as potent agents for PONV in adult patients, but even if approved in pediatrics, it seems likely a multiple agent approach to PONV as described previously will remain the standard of care. Updated practice guidelines for postanesthetic care from the American Society of Anesthesiologists (ASA) in 2012 support the practice of giving multiple agents for prophylaxis of PONV.[107]

For PONV that occurs despite prophylaxis, rescue treatment should be initiated using a class of drug different from that given prophylactically. If no prophylaxis was given, then a low-dose 5-HT3 antagonist is recommended. There is evidence to show that there is no benefit to repeating the prophylaxis therapy within 6 hours after the first dose. Options for rescue therapy include metoclopramide, dimenhydrinate, perphenazine, or droperidol.[78,122,124] Because of the potential for QT prolongation and torsades des pointes, droperidol should be reserved for patients who have failed first-line therapy and are hospital inpatients.[122] Unlike recommendations to use multiple agents for PONV prophylaxis, the 2012 guidelines on postanesthetic care from the ASA find literature to be inadequate to recommend multiple agents compared to a single agent for the treatment of ongoing nausea and vomiting despite prophylaxis.[107] Other contributing factors to consider when assessing ongoing PONV include postoperative ileus, opioid use, blood draining down the throat, and bowel obstruction.

Acknowlegment

We gratefully acknowledge the contribution of Louis L. Bystrak, Ann Marie Heine, Kelly A. Michienzi, and Sasko D. Stojanovski, who authored this chapter in previous editions.

CHAPTER 99

Acute Liver Failure, Liver Transplantation, and Extracorporeal Liver Support

Simon Horslen, Hengqi (Betty) Zheng

PEARLS

- Pediatric liver failure represents a large number of heterogenous etiologies.
- Effective diagnosis requires a systemic approach, but in spite of thorough workup, currently in a large proportion of cases, cause cannot be determined.
- Prognostication is remarkably difficult in that spontaneous recovery has occurred even in patients with advanced hepatic necrosis, deep coma, and severe coagulopathy. Prognostic tools have been designed, but all have been found to be fallible and clinical experience is invaluable.
- Extracorporeal liver support has been tried in many forms from simple exchange transfusion to bioartificial liver support technologies, and although research is ongoing, none have been demonstrated to alter outcomes, either in terms of survival with native liver or getting more patients to successful liver transplantation.
- Orthotopic liver transplantation is lifesaving, and early transfer to an experienced liver transplant center is advisable for all children with coagulopathy secondary to acute liver disease.
- Many patients can be extubated immediately after the liver transplant operation or promptly following admission to the pediatric intensive care unit.
- Oversedation is to be avoided because it increases the risk of complications and prolongs ICU stay and total length of hospital stay after liver transplantation.
- Close monitoring of fluid balance in the first few days of liver transplantation facilitates optimal recovery, faster weaning from artificial ventilation, and possible shorter ICU stays.
- Anticipation and early recognition of postoperative complications through

awareness, suspicion, and appropriate testing, together with prompt and aggressive treatment of complications, maximize possibilities of rescuing both the patient and allograft.

Introduction

Liver failure is an unusual issue in most pediatric intensive care unit (PICU) settings, but expert management is crucial to achieving optimal outcomes, which may include liver transplantation. This chapter focuses on acute liver injury and transplantation. The management of the end-stage and life-threatening complications of chronic liver disease is beyond the scope of this chapter but deserves equal study and experience for optimal care.

Acute Liver Failure

Background/Definitions/Outcomes

Pediatric acute liver failure (PALF) is a life-threatening condition where previously healthy children lose hepatic function rapidly, requiring immediate medical attention and careful monitoring.[1] PALF represents a heterogeneous condition with a broad range of etiologies including infections, toxin- and drug-related injuries, metabolic disorders, immunologic, ischemic, and irradiation damage. Despite the many known causes of PALF, a specific etiology is not determined in up to 50% of cases.[1-5] Management consists of supportive measures, with a focus on anticipation, prevention, and treatment of complications along with early consideration for liver transplantation.[6-10] Timely intervention to treat the metabolic derangements associated with acute liver failure is pivotal and can help mitigate the morbidity associated with this condition.[11-16] In the United States, the incidence of PALF has been estimated at 17 cases per 100,000 per year.[17]

Liver failure is defined as the loss of normal liver function that includes synthesis of serum proteins including clotting factors and albumin, metabolism and storage of glucose and fatty acids, and detoxification and excretion of exogenous and endogenous molecules such as drugs and products of protein metabolism, most notably ammonia. Evidence of liver failure is reflected in elevations of the prothrombin time, bilirubin, and ammonia. In adults, the traditional definition of acute or fulminant liver failure is the onset of hepatic encephalopathy within 8 weeks of the first signs of liver disease. Such definitions are difficult to apply to children and infants because children are relatively resistant to encephalopathy, which may only become apparent, if at all, at a very late stage of the disease, and because of the difficulty inherent in identifying encephalopathy, even if present, in the young child. Subacute liver failure has been defined as the development of hepatic encephalopathy after 8 weeks and before 24 weeks from the onset of liver disease in the absence of preexisting chronic liver disorders.

To determine outcomes, investigate prognostic factors, and further decipher etiologies, the Pediatric Acute Liver Failure Study Group (PALF-SG) involving 24 pediatric liver centers in the United States, Canada, and England formed in 1999. The study's entry criteria include evidence of hepatic injury without known chronic liver

disease manifesting as an international normalized ratio (INR) of 1.5 and encephalopathy or INR of 2.0 with or without encephalopathy.[18] Although it is tempting to use the criteria to define PALF, this set of standards was meant to capture pediatric patients who are at risk of developing PALF relatively early in their clinical course and should not be used as a general definition. The group has reported data on 348 subjects over a 6-year period and concluded that survival and the need for liver transplantation depend on age and diagnosis.[18] For established PALF etiologies, between 20% and 33% received a liver transplant versus 46% in indeterminate cases, whereas spontaneous recovery ranged from 46% to 60%.[18]

Diagnosis and Workup

The causes of PALF vary with the age of the child; however, acute liver failure of indeterminate cause is common in all age groups, accounting for 40% of PALF among patients younger than age 3 years and 60% in those age 3 years and older.[18] The large number of indeterminate causes is due to several factors including hepatic improvement prior to finishing clinical workup, lack of current available testing for all etiologies, or lack of a thorough workup. The term *indeterminate etiology* should prompt further investigation.

Of the known etiologies, severe hepatitis from echovirus, adenovirus, and herpesvirus is recognized in the neonatal population. Metabolic liver disease and hemophagocytic lymphohistiocytosis are diagnoses usually made in infants. Acute hepatitis A and B infections are rare causes of PALF in North America but are a common cause of PALF in school-aged children in developing countries.[19] Drug-induced liver disease is more common in older children, especially secondary to intentional acetaminophen overdose[18] (Table 99.1).

TABLE 99.1

Intensive Care Unit Management

No Sedation Except for Procedures
Lines and Tubes
• Multilumen central venous catheter • Arterial tube • Nasogastric tube • Urinary Foley catheter • Bed scale
Monitor
• Heart and respiratory rate • Arterial BP, CVP • Core/toe temperature • Neurologic observations • Gastric pH (>5) • Blood glucose (>4 mmol/L) • Acid-base • Electrolytes • PT, PTT
Fluid Balance
• 75%-95% maintenance • Dextrose 10%-25% • Sodium (2–3 mEq/kg/day)
Maintain Circulating Volume With Colloid/FFP
Coagulation Support Only If Required
Drugs
• Vitamin K • H_2 antagonist

• Antacids • Lactulose • *N*-acetylcysteine for acetaminophen toxicity • Broad-spectrum antibiotics • Antifungals
Nutrition
• Enteral feeding (1–2 g protein/kg/day) • PN if ventilated

BP, blood pressure; *CVP*, central venous pressure; *FFP*, fresh frozen plasma; *PN*, parenteral nutrition; *PT*, prothrombin time; *PTT*, partial thromboplastin time.

Prognostic Assessment

Several attempts to produce prognostic tools based on a snapshot of clinically available data either at presentation or at peak values have been attempted, but all have been found wanting. Three of the more often quoted include the King's College Hospital Criteria (KCHC), the liver injury unit (LIU) score, and the Clichy criteria. The Clichy criteria are primarily derived from adult patients with acute hepatitis B infection, and thus the utility in the pediatric population has always been in doubt.[20] KCHC applied to the PALF-SG cohort fails to reliably identify those patients at risk of death.[18] The LIU score predicted those who eventually underwent transplantation but was not a reliable predictor of death.[21] This is not particularly surprising as the LIU calculation is based on levels of bilirubin, ammonia, and prothrombin time (PT), all of which are used clinically to determine who might benefit from transplantation and as such were self-fulfilling predictors.[21] All of these tools suffer from the fact that no account is taken for the dynamic nature of PALF, and further work would benefit from examining the trends over time rather than data at a single time point.[22,23]

Pediatric Intensive Care Unit Management

The care team should obtain a full history including information about infectious illnesses, behavior changes, the time course of the development of jaundice, and foreign travel. It is important to establish what medications the child has taken, including over-the-counter preparations, acne medications, folk remedies, Chinese herbs, and herbal supplements, as well as determining what other medications might be in the household.[24] In adolescents, inquiries should be made about the use of illicit drugs, potential for self-harm, and sexual contact.

Acute hepatic dysfunction often first manifests as jaundice and general malaise. Hepatomegaly may be present, but the liver edge is frequently soft and difficult to palpate. Splenomegaly is unusual, and its presence may point to a metabolic or hematologic diagnosis. Petechiae or ecchymoses can be associated with coagulopathy. The patient's level of consciousness and degree of hepatic encephalopathy (Table 99.2) should be established using a reliable scale,[3,25,26] and a complete central nervous system examination should be performed including examination of reflexes and mental status. Parental help in the assessment of mental status is perhaps one of the best indicators of deviation from baseline neurologic status. Serial neurologic examinations should be conducted once the baseline is established to identify any progression of encephalopathy. Attention must be paid to heart rate, blood pressure, edema, and peripheral perfusion, recognizing that increased intracranial pressure can lead to a Cushing triad of hypertension, bradycardia, and irregular breathing pattern. Work of breathing should be assessed

and assisted with positive pressure or mechanical ventilation if needed for adequate ventilation and oxygenation. Monitoring of and, if necessary, intervention for glycemic control, acid-base balance, and adequate tissue perfusion should be included in the care plan. Antibiotics and antiviral medications should be started if an infectious cause is suspected.

TABLE 99.2

Causes of Pediatric Acute Liver Failure

Viral	Hepatitis A cytomegalovirus Hepatitis B paramyxovirus Hepatitis D adenovirus Hepatitis E enterovirus Herpes simplex Parvovirus B19 Varicella zoster virus Severe acute respiratory syndrome Epstein-Barr virus Hemorrhagic fever virus
Bacterial	Septicemia Bartonella Leptospirosis Rocky Mountain spotted fever Salmonella typhi/paratyphi
Metabolic	Hereditary fructose intolerance Carnitine defects Urea cycle disorders Wilson disease Organic acidemias Tyrosinemia type 1 Fatty acid oxidation defects Niemann-Pick type C Mitochondrial disorders Acute fatty liver of pregnancy
Immune	Autoimmune hepatitis Hemophagocytic lymphohistiocytosis Neonatal hemochromatosis Autoimmune hemolytic anemia with giant cell hepatitis
Toxic	Drugs/toxins/herbal Amanita phalloides
Vascular	Budd-Chiari postcardiac surgery Veno-occlusive disease Liver trauma Ischemic hepatitis/shock liver
Neoplastic	Leukemia Lymphoma Hepatocellular carcinoma
Other	Reye syndrome Massive liver resection Hypothermia Sickle cell anemia Heat stroke

A central venous catheter should be placed for administration of glucose containing intravenous fluids and colloids and for frequent blood draws. Placement of an arterial line should be considered for patients with clinical deterioration or with hepatic encephalopathy.[17] Urinary catheter placement can also be considered to ensure accurate fluid balance estimation (Table 99.3).

TABLE 99.3

Clinical Stages of Hepatic Encephalopathy

Stage	Asterixis	EEG Changes	Clinical Manifestations

0	None	None	Normal
I (prodrome)	Slight	Infant/child: Difficult or impossible to test adequately Adult: Normal or diffuse slowing to theta rhythm, triphasic waves	Infant/child: Inconsolable crying, child not acting like self to parents Adult: Mild intellectual impairment, disturbed sleep-wake cycle
II (impending)	Easily elicited	Infant/child: Difficult or impossible to test adequately Adult: Generalized slowing, triphasic waves	Infant/child: Inconsolable crying, child Adult: Drowsiness, confusion, coma/inappropriate behavior, disorientation, mood swings
III (stupor)	Present if patient cooperative	Infant/child: Difficult or impossible to test adequately Adult: Grossly abnormal slowing of rhythm, triphasic waves	Infant/child/adult: Drowsy, unresponsive to verbal commands, markedly confused, stupor, combative, hyperreflexia, positive Babinski sign
IV (coma)	Usually absent	Infant/child/adult: Appearance of delta waves, decreased amplitudes	Infant/child/adult: Unconscious, decerebrate, or decorticate response to pain present (stage IVA) or absent (stage IVB)

A workup for PALF with investigations reflecting age-dependent etiologies is suggested in Table 99.4. Initial monitoring blood work should include complete blood count, blood gases, glucose, electrolytes, aminotransferases, prothrombin time/INR, creatinine, bilirubin, and ammonia. Monitoring blood work should be repeated every 6 to 12 hours until the clinical course is determined. If it is considered that the patient may require liver transplantation, a transplant workup should be initiated (Table 99.5).

The presence of impaired central nervous system function with acute liver disease represents an indication for immediate admission to the PICU. The decision to transfer a patient with evolving signs of progressive liver failure must be made in a timely manner, because the risks of transporting patients in a deteriorating condition can be substantial. Referral to a pediatric liver transplant center should ideally be made prior to clinical decompensation. Families of children with acute liver failure sometimes require a considerable amount of psychologic support and counseling. The best approach to management of PALF is as a team, with collaboration among specialists in hepatology, critical care medicine, transplant surgery, and early consultation by other specialties such as biochemical genetics, neurology, neurosurgery, and nephrology as appropriate.

Specific Treatments for Particular Causes of Pediatric Acute Liver Failure

Acetaminophen Toxicity

Acute acetaminophen overdose was noted in 14% of all children from the PALF-SG as the most common identifiable cause of PALF in children ≥3 years.[18] Two clinical presentations were identified: acute intentional ingestion and a *therapeutic misadventure,* which refers to the ingestion of multiple doses exceeding daily total recommended dosing taken over a period of time to treat clinical symptoms.[1] The potential severity of hepatic damage can be assessed using the Rumack-Matthew nomogram and serum acetaminophen concentration. Administration of intravenous *N*-acetylcysteine (NAC) should not be delayed if there is reason to suspect significant hepatic injury from the ingestion.

Amanita Poisoning

Amatoxin is a hepatotoxin found in wild mushrooms, particularly the *Amanita* and *Galerina* species, although the majority of significant poisonings are due to the ingestion of *Amanita phalloides,* the death cap mushroom. Once ingested, amatoxin binds to DNA-dependent RNA polymerase type II and decreases intracellular protein synthesis, leading to hepatocyte apoptosis.[27,28] Prompt gastrointestinal decontamination with activated charcoal and supportive management with fluids should be initiated ideally within 24 hours of ingestion. High-dose penicillin G can disrupt hepatocellular uptake of amatoxins. NAC and silibinin have been suggested as potential therapies, although definitive trial data are lacking.

Autoimmune Hepatitis

Although autoimmune hepatitis usually presents as chronic liver disease, a small percentage will present with PALF. Elevations in autoimmune antibodies (antinuclear antibody, antismooth muscle antibody, liver-kidney microsomal antibody, soluble liver antigen) and total IgG level can help decipher the diagnosis. Liver biopsy is very helpful if it can be conducted safely. If autoimmune hepatitis is suspected, initiation of intravenous corticosteroids can be expected to alter the course of disease progression and avoid the need for transplantation.

Wilson Disease

Wilson disease (WD) in the setting of PALF can be a difficult diagnosis. Serum ceruloplasmin may be falsely low in non-WD PALF due to poor synthetic function or falsely elevated due to acute phase reaction in WD. A Coombs-negative hemolytic anemia is almost always present along with an elevated serum bilirubin. Transaminases and alkaline phosphatase may be relatively low and the ratios of alkaline phosphatase (IU/L)/bilirubin (mg/dL) <4 and aspartate transaminase (AST)/alanine transaminase (ALT) >2.2 may suggest the diagnosis.[29] Mutational analysis is currently the most reliable method of making the diagnosis, but many centers do not have the ability to get this testing completed in a timely manner to be helpful in the acute setting. The WD score, which incorporates AST, serum bilirubin, white blood cell count, and PT, can be used to determine prognosis.[30] Chelation therapy should be initiated with D-penicillamine or more commonly now with

trientine.

Metabolic Disease

Undiagnosed metabolic disorders account for about 10% of PALF patients, mostly in infants.[18] Urea cycle defects can also present with the features of acute liver failure early in life. Speedy and reliable diagnosis can lead to early supportive care and appropriate treatment. For some metabolic liver disease such as fatty acid oxidation defects, medical management can be the mainstay of treatment with liver transplantation as a last resort. In diseases such as mitochondrial cytopathies, with multisystem involvement, transplantation will not alter nonhepatic disease progression and may be futile.

Glucose, Electrolytes, and Fluid Balance

The goal of fluid balance is to maintain hydration and renal function without worsening or provoking cerebral edema. Fluid input should be 75% to 95% of normal maintenance requirements in normotensive patients. Intravenous fluids, electrolytes, specifically potassium, phosphorus, calcium, and magnesium should be monitored carefully and replaced if necessary.

Hypoglycemia may occur due to the failure of hepatocytes to sustain glucose synthesis and release compounded by hyperinsulinemia from diminished hepatic degradation and secondary bacterial infection.[31-34] Frequent bedside monitoring of blood glucose concentrations and the intravenous administration of glucose may prevent this complication. Hypoglycemia should be treated with titration of continuous glucose infusions. The support of a nutritionist to help with energy calculations and parental therapy in the ICU setting is valuable.

Urine output should be monitored for oliguria whether from prerenal or renal causes. If renal perfusion is adequate, loop diuretics and vasoactive-inotropic agents can be used to maintain urine output. Should oliguria be unresponsive to additional fluids, early consideration should be given to renal replacement therapy (see also Chapter 78).

Central venous pressure monitoring is helpful for assessing and maintaining organ perfusion. Inotropic support frequently becomes necessary in advanced liver failure with the onset of hypotension in association with multiple organ failure. Permissive hypertension, especially in the setting of cerebral edema, may help maintain cerebral perfusion pressures.

Ascites

Excessive peritoneal fluid accumulation can be found in many patients with PALF, due to the combined effects of acute portal hypertension, lobular collapse, vasodilatation, poor vascular integrity, and reduced oncotic pressure. Clinically evident ascites occurs in less than half the patients but may be a site for secondary bacterial or fungal infection. Treatment is rarely needed in the acute setting but includes albumin infusions and judicious use of diuretics. Paracentesis may be indicated if peritonitis is suspected.

Coagulopathy

The liver plays a crucial role in the synthesis of clotting factors (factors I or fibrinogen, II or prothrombin, V, VII, IX, and X) and fibrinolytic factors (antithrombin III, protein C, protein S).[35,36] In PALF, impairment is evident in the actions of both clotting and fibrinolysis. Often administering vitamin K parenterally is trialed early on in the course to ensure that coagulopathy is not due to vitamin deficiency, but it rarely improves coagulation in PALF.

The PT and thus the INR depend immediately on the availability of factor VII, which has the shortest half-life of the clotting factors. Measurement of factor VII may be a more sensitive indicator than the prothrombin time but is typically not as readily available. Fibrinogen concentrations can also be decreased because intravascular coagulation is present in addition to factor deficiencies in almost all PALF patients, indicating ongoing thrombosis. Sepsis may also be present as an additional cause of disseminated intravascular coagulation (DIC).

Coagulopathy should be managed conservatively to avoid fluid overload. Oozing from needle puncture sites and line insertion is common and usually should not necessitate transfusions. Petechiae reflect decreased platelet function, disturbed vascular integrity, or DIC. Treatment with fresh frozen plasma, cryoprecipitate, and platelet infusions is indicated for active bleeding and invasive procedures (see also Chapters 91 through 93). Spontaneous bleeding is unusual because both pro- and anticoagulation factors are deficient. In spite of this, most programs pick an arbitrary cutoff above which product is infused—for example, an INR of >5—although no cutoff level is well supported by the literature. Administration of recombinant factor VIIa may be useful in preparation for invasive procedures if coagulopathy is unresponsive to other blood products.[37]

Gastrointestinal tract hemorrhage secondary to gastritis or stress ulceration can be life threatening. Proton pump inhibitors or high-dose histamine receptor 2 antagonists should be administered intravenously to reduce the risk of upper gastrointestinal bleeding.

Neurologic Status (Encephalopathy and Cerebral Edema)

Neurologic status should be monitored clinically; classification of the stages of hepatic encephalopathy (HE) is based on clinical findings, which may be augmented by EEG changes (see Table 99.4). Computed tomography scans are not generally useful early in encephalopathy other than as a baseline examination to be compared with subsequent imaging to evaluate for signs of cerebral edema later in the disease. The mainstay for monitoring progression of encephalopathy is frequent serial neurologic examinations. Transcranial Doppler ultrasound is a noninvasive tool to monitor middle cerebral artery blood flow velocity. CT of the head without contrast can be beneficial to evaluate intracranial herniation or intracranial bleeding but is not especially sensitive to the degree of cerebral edema (Fig. 99.1). Direct intracranial pressure monitoring (ICP) is the most sensitive and specific measure of ICP but increases the intracranial bleeding risk, has not been demonstrated to alter outcome, and the use of ICP monitors in PALF depends largely on individual center practices.

FIG. 99.1 CT showing cerebral edema in child with acute liver failure. Note the reduction in ventricular volume, effacement of sulci, and alteration in gray-white differentiation. Intracranial pressure monitoring device in left frontal lobe.

Acute HE is defined as changes in consciousness that occur as a result of acute hepatic dysfunction, in the absence of other factors such as sedative medications, intracranial hemorrhage, or metabolic disturbances. From the PALF-SG, HE was present in 50% of children upon admission into the study and increased to 65% during the first 7 days.[18] The rate of progression is variable, but it may increase rapidly within hours of presentation to coma and be associated with the development of fatal cerebral edema. Although trending ammonia can be helpful to indicate the trajectory of HE, the serum level does not predictably measure the degree of or development of HE.

Drowsiness and lethargy or irritability and inconsolability become readily apparent as the patient progresses into stage II hepatic encephalopathy. Inappropriate behavior with outbursts of anger or crying may develop. Impaired motor coordination such as ataxia, dysarthria, apraxia, hyperreflexia, sustained clonus, rigidity, extensor posturing, and bizarre facial expressions become evident. Stage III hepatic encephalopathy is distinguished by progressive somnolence and stupor. The patient is arousable by vigorous physical stimuli but is disoriented, does not respond to commands, and does not recognize family members.[17] Intubation and ventilation may be needed as the patient approaches grade III or if patients become combative and a danger to themselves or others. Progression into stage IV hepatic encephalopathy is defined by the presence of coma. The patient responds only to painful stimuli. In deeper stage IV, the patient may exhibit decerebrate posturing with the loss of brain stem reflexes.

Acute hepatic encephalopathy is considered to be completely reversible after resolution of the hepatic dysfunction as long as cerebral edema and poor brain perfusion has not caused neuronal injury, although long-term neurodevelopmental

studies are only now being conducted.

Cerebral Edema

Cerebral edema may develop during or beyond stage III encephalopathy and progress within hours of the onset of coma. Brain death associated with cerebral edema contributes to reduced survival after liver transplantation along with increased overall mortality.[15,38-41]

The pathogenesis of cerebral edema involves the interaction of ammonia, other hepatic toxin metabolites, and cerebral blood flow. Ammonia crosses freely into the brain where astrocyte glutamine synthase converts glutamate to glutamine. Glutamine acts as an active intracellular osmole leading to astrocyte swelling, cerebral edema, and increased intracranial pressure. Homeostatic mechanisms attempt to maintain perfusion by increasing systemic vascular resistance. Cerebral perfusion pressure is calculated as the difference between mean arterial pressure and intracranial pressure.[42] Evidence also supports the belief that glutamine acts as a carrier of ammonia into the mitochondria where the accumulation leads to oxidative stress and contributes to further to astrocyte swelling.[42]

Management of Hepatic Encephalopathy and Cerebral Edema

Lactulose, a nonabsorbable disaccharide, may be administered orally or via the nasogastric tube. Lactulose is fermented by intestinal flora to lactic acid, acidifying the bowel contents and limiting the absorption of the ammonium ion. The nonabsorbable antibiotic rifaximin is commonly used to reduce ammonia production by colonic bacteria, replacing the traditional use of enteral aminoglycoside antibiotics, particularly neomycin.[43] Limiting protein intake to 0.5 to 1 g/kg/day whether enterally or parenterally has also been recommended.

If the encephalopathy progresses to compromise respiratory drive, elective intubation and mechanical ventilation should be undertaken. If sedation is required, either for restraint or during procedures, short-acting barbiturates or opiates can be used. Benzodiazepines should be avoided because the γ-aminobutyric acid (GABA) receptor has been implicated in the development of encephalopathy.

When cerebral edema is apparent, careful fluid restriction, permissive hypertension, adequate oxygen saturation, and head elevation of 20 to 30 degrees are all basic supportive measures. If intracranial pressure monitoring is available, ICPs should be maintained ≤20 mm Hg with cerebral perfusion pressure 50 ≥50 mm Hg. Hypertonic saline 10% to 30% and mannitol have been used to lower increased ICPs (see also Chapter 66).[17] Serial measurements of serum osmolality to avoid concentrations >320 mOs/L are recommended, especially if there is evidence of renal compromise.[44]

Ventilation

Ventilatory support is required in all patients who progress to stage III encephalopathy and some who due to combativeness in stage II are at risk of injuring themselves. The need for support may be precipitated by the injudicious use

of sedative medications, particularly benzodiazepines, which should be avoided in unventilated patients with PALF. At the onset of PALF, patients usually have normal pulmonary compliance, and hyperventilation should be avoided. As the disease progresses, pulmonary edema and acute respiratory distress syndrome (ARDS) may alter this situation, in which case careful and frequent monitoring of blood gases and ventilation status are vital. Although hyperventilation may temporarily reduce ICP, the effect is not sustained and prolonged use is not recommended.

Infection Prophylaxis and Treatment

The majority of adults and a lesser proportion of children develop infection that may be related to impairment of cellular and humoral immune systems from liver dysfunction.[45,46] The organisms most often implicated are gram-positive bacteria, presumably of skin origin. Gram-negative bacteria or a fungal infection is occasionally observed.

Management includes surveillance cultures from the endotracheal tube, indwelling catheters, and urine. Broad-spectrum antibiotics should be started at the first suspicion of sepsis, as the signs may be subtle and fever may be absent as part of the immune paralysis seen with advanced liver failure. When fungal infection is suspected, antifungals such as fluconazole or micafungin should be included. Positive cultures in the absence of clinical infection should result in removal or replacement of the infected catheter and administration of the appropriate antimicrobials.

Renal Function

Acute kidney injury from prerenal azotemia, acute tubular necrosis (ATN), and hepatorenal syndrome can complicate the course of PALF.[47] Prerenal azotemia is commonly due to dehydration and more rarely gastrointestinal bleeding. A marked increase in blood creatinine concentration may develop from decreased glomerular filtration or increased muscle breakdown. Acute tubular necrosis is seen in the minority of patients and may occur because of hypovolemia. Laboratory abnormalities indicating a diagnosis of ATN include abnormal urinary sediment, urinary sodium concentration greater than 20 mmol/L, reduction in creatinine clearance (urine/plasma creatinine ratio <10), and oliguria (urine output <0.5 mL/kg/h). Hepatorenal syndrome is a common cause of renal insufficiency in adults with acute liver failure (ALF) but is unusual in PALF. The pathophysiology is multifactorial involving electrolyte imbalance, sepsis, and hypovolemia. Laboratory evaluation reveals sodium retention (urinary sodium concentration <20 mmol/L), normal urinary sediment, and reduced urinary output (<1 mL/kg/h).

The aim of renal management is to maintain circulating volume to prevent hypovolemia and ensure that urine output is greater than 0.5 mL/kg/h without fluid overload. If there are signs of oliguria, a volume expander can be given one time at 10 mL/kg. If there are signs of fluid overload, the use of furosemide doses or infusion may be effective. Severe oliguric renal failure often requires hemodialysis or continuous renal replacement therapy (see also Chapter 78).

Although acute renal failure usually recovers quickly after liver transplantation,

acute tubular necrosis may severely complicate the postoperative management.[48,49] Even in patients who require hemodialysis or continuous renal replacement therapy, renal function usually returns to normal after successful liver transplantation.

Liver Support

Extracorporeal liver support (ECLS) for patients with ALF has a history that dates back before liver transplantation was an option, but despite elegant clinical experiments with ex vivo liver perfusion or cross-circulation with human volunteers or animals, no evidence for increased survival was apparent.[50-53] Despite the successes of transplantation, the relative shortage of organs and the need to bridge a patient until an allograft becomes available have maintained interest in extracorporeal support for ALF. In general, ECLS systems can be categorized as either purely nonbiological filtration and detoxification systems or with the addition of a cellular component designed to replace some of the synthetic function of the liver, biologic hepatic functional replacement.

Small molecular weight solutes such as urea and ammonia can be cleared equally effectively with convective (continuous venovenous hemofiltration [CVVH]) or diffusive (continual venovenous hemodiafiltration [CVVHD]) approaches.[54] The goals for continuous renal support in ALF are to optimize fluid management and nutrition, correct electrolyte disturbances, maintain a balanced state between anticoagulation and coagulopathy, control ammonia levels, and remove potentially toxic substances not eliminated by the injured liver. Patients may require little to no anticoagulation because of the underlying coagulopathy.[55] The decision to use no anticoagulation, heparin, or citrate anticoagulation is based on local experience and preference. Many programs have used citrate,[56,57] which binds calcium within the hemofiltration circuit decreasing its availability as a cofactor in the clotting cascade. Calcium is infused back to the patient distal to the hemofiltration circuit to prevent hypocalcemia. Laboratory evidence for citrate lock, which represents residual citrate in the patient as the delivery of citrate exceeds its hepatic clearance, is rising total serum calcium with a falling ionized serum calcium level. Experience has also shown that the use of intraoperative hemofiltration during liver transplantation is safe and effective.

Although simple hemofiltration or dialysis can remove ammonia and other water-soluble molecules, a large number of potentially toxic hydrophilic and protein-bound molecules are not cleared. To remove these substances, exchange transfusion, large volume plasma exchange, and dialysis with an albumin-containing dialysate have been undertaken. Both to limit the waste of human-derived blood products and to improve the tolerability of the procedures, systems have been designed to remove the toxins by passing the separated blood fractions through activated charcoal or resin columns and returning the “cleaned” fraction to the patient in closed recycling systems such as the molecular absorbent recirculating system (MARS), using albumin dialysis, and Prometheus, which utilizes plasma fractionation. Although there are no randomized controlled studies to report efficacy of Prometheus versus MARS, there is some clinical indication that Prometheus could have a higher efficiency in toxin removal and normalization of serum lab values, although neither have proved the ability to improve overall survival.[58-60]

Bioartificial liver devices differ from toxin removal systems in that they contain a

cell-housing bioreactor, which contains functional liver cells to replace the function of the damaged liver. Two such systems that have undergone randomized control trials are HepatAssist and the Extracorporeal Liver Assist Device (ELAD). The HepatAssist utilized porcine hepatocytes in conjunction with plasmapheresis, toxin absorption, and an oxygenator. In contrast, ELAD utilizes HepG2 cells, a hepatoblastoma-derived immortalized cell line, along with hemofiltration, toxin absorption, and an oxygenator. Neither system is currently available for further clinical trials, but development continues[61,62] (Fig. 99.2).

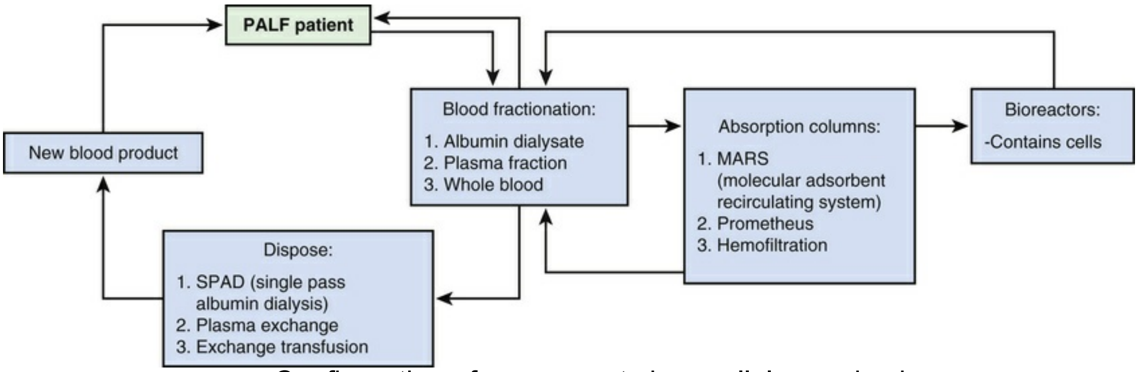

FIG. 99.2 Configuration of components in parallel or series in extracorporeal liver support (ECLS) whether nonbiological filtration devices without a cell-housing bioreactor or bioartificial liver devices with a cell-housing bioreactor.

Liver Transplantation

Background/History/Terminology

Although the first liver transplant was performed by Dr. Thomas Starzl and his team in 1963, it was not until the development of cyclosporine that the 1-year recipient survival substantially increased, launching liver transplantation as a standard treatment for hepatic failure. Immunosuppression therapy evolved from steroid and azathioprine therapy in the 1970s to today's array of immunosuppressive agents, the mainstay of which is tacrolimus but also included are antilymphocyte globulins, rapamycin derivative, and mycophenolate.

Whole organ liver transplantation remains the most commonly performed of these procedures, but it is associated with significant size limitations in regard to children. The use of reduced size transplantation with left lateral segment or left lobe is common practice for pediatric patients. In split liver procedures, the division of one donor liver into two allografts can provide a smaller pediatric patient with the left lateral segment allograft and an adult or larger pediatric patient with a right lobe allograft. Living donor liver transplantation, with the procurement of usually the left lateral segment for pediatric patients, is also an option.

Indications for Liver Transplant

The indications for liver transplantation include (1) liver disease that is immediately

limiting survival such as PALF, decompensated chronic liver disease, and malignant hepatic tumors; (2) liver disease leading to poor quality of life from pruritus, poor growth, and development; and (3) metabolic liver disease with extrahepatic complications such as urea cycle defects, oxalosis, and Crigler-Najjar syndrome.[17] According to the Studies of Pediatric Liver Transplant Registry (SPLIT), between 1995 and 2007 the reasons for transplantation were cholestatic liver disease (mainly biliary atresia) in 53.9%, metabolic disease in 15%, PALF in 14%, cirrhosis/end-stage liver disease in 6.7%, tumor in 6.7%, and hepatotoxic injury in 3.5%. [63] Absolute contraindications to liver transplantation include unresectable primary extrahepatic malignancy, progressive terminal nonhepatic disease, and uncontrolled systemic sepsis.[17]

As discussed earlier, there is no good prognostic test for those who will need liver transplantation in patients with PALF. The use of indices such as KCHC and LIU score may offer guidance, but ultimately the decision becomes a matter of judgment by an experienced transplant team.

Pretransplant Workup/Evaluation

Along with the investigations outlined in Table 99.5, the evaluation of a child for liver transplantation requires that the team prepare and educate the patient and family in regard to the pre-, peri-, and postoperative stages of the transplant journey, which includes waiting time, general information on source of donor organs, the operation itself and potential technical complications, postoperative care, and long-term outcomes and complications. This requires care and experience with clear protocols that ensure consistency. In cases of ALF, the time available for such detail is severely constrained, but it is still imperative that the complete evaluation process is undertaken.

Organ Allocations

Deceased donor organs are allocated to a particular recipient based on strict rules adopted by United Network for Organ Sharing (UNOS), the organization tasked by Health Resources and Services Administration (HRSA) to administer the Organ Procurement and Transplantation Network (OPTN) within the United States. The rules determine the recipient based on urgency, geography, blood group matching, and donor age. The highest urgency is status 1A and applies to patients with ALF and an acutely failing allograft immediately posttransplant due to complications such as primary nonfunction. Status 1B is confined to pediatric age groups and is for decompensated chronic liver disease, hepatoblastoma, and hyperammonical inborn errors for metabolism such as urea cycle disorders. The severity scores for all other patients are ranked according to their Model for End-Stage Liver Disease (MELD) score for adults and adolescents or their Pediatric End-Stage Liver Disease (PELD) score for patients <12 years of age (Table 99.6).

TABLE 99.6

Model for End-Stage Liver Disease (MELD)/Pediatric End-Stage Liver Disease (PELD) Calculations

PELD = 0.480 Log_e Bilirubin (mg/dL)
+1.857 Log_e INR
–0.687 Log_e Albumin (g/dL)
+0.436 if patient is less than 1 yo
+0.667 if patient has growth failure ≤2SD
MELD = 0.957 Log_e Creatinine (mg/dL)
+0.378 Log_e Bilirubin (mg/dL)
+1.120 Log_e INR
+0/643

Technical Aspects of Liver Transplantation

Although the details of the liver transplantation operations are beyond the scope of this chapter, there are principles of liver transplantation that should be understood. Foremost in reducing intraoperative and postoperative morbidity, it is important to send the patient for transplantation in the best condition possible. This means that (1) infections have been treated, (2) excess edema has been avoided or resolved, (3) cardiopulmonary and renal systems are functioning well, and (4) the brain has been spared irreversible damage.

The first step intraoperatively is to remove the native liver. Complicating this procedure may be the presence of portal hypertension and adhesions from previous surgeries. Addressing donor liver hepatic vein outflow is the first step in implanting the new liver, usually with a connection to the native inferior vena cava either with interposition of the donor inferior vena cava or using a “piggyback” technique. Next is the establishment of adequate arterial inflow with an appropriately sized arterial connection. Typically this is with the recipient hepatic or celiac artery to donor hepatic artery if possible, but otherwise an anastomosis to the recipient aorta is made. Portal vein anastomosis often requires accommodation for differences in caliber between donor and recipient portal veins. Biliary anastomosis is either from native to donor bile duct or by implantation of donor bile duct into a Roux-en-Y jejunal limb if the duct-to-duct method is not feasible. Closure of the abdomen should minimize increased intraabdominal pressures so as to not compromise blood flow to the allograft, sometimes requiring an open abdomen and delayed abdominal wall closure. Intraoperative, immediate postoperative, and serial Doppler ultrasound studies are used to assess blood flow within the transplanted liver.[64]

Technical Complications

Primary nonfunction (PNF) of the graft is severe dysfunction of the liver in the absence of vascular thrombosis and is a disastrous complication necessitating immediate retransplantation. Of children with graft failure within 30 days, primary graft dysfunction accounted for 25.6% of cases.[65] The etiology of PNF is unknown but thought to be related to ischemia-reperfusion injury. Evidence of PNF includes worsening coagulopathy, acidemia, rising liver enzymes, and cholestasis. All measures used to support a patient with minimal liver function should be

considered and instituted because the condition will become rapidly fatal without retransplantation.[66]

Hepatic artery thrombosis (HAT) may occur at anytime after transplantation, but if it occurs within the first few day posttransplantation it commonly severely compromises the allograft and emergent retransplantation may be necessary. HAT occurring later tends to be better tolerated because of the dual hepatic blood inflow (hepatic artery [HA] and portal vein [PV]). Hepatic artery thrombosis, occurring in 2% to 10% of liver transplants overall, can, in addition to early graft failure, lead to biliary leaks, ischemic cholangiopathy with stricture formation, and intrahepatic abscess.[63] Etiologies include poor arterial inflow, technical complications with the anastomotic site, graft edema, hypercoagulable states, and overtransfusion. Routine assessment of hepatic artery patency using color Doppler ultrasonography at the bedside is critical during this period. Prompt recognition of HAT early after implantation and intervention with anticoagulation and possibly surgical thrombectomy and revision of the arterial anastomosis is critical if the allograft is to be saved.

Portal vein thrombosis (PVT) is uncommon and occurs in <5% of pediatric liver transplants. PVT occurring early after transplantation can be seen in association with PNF or share common risk factors with those associated with HAT. Treatment is centered on anticoagulation and surgical intervention with thrombectomy, thrombolysis, or shunt placement. Late PVT results in obstruction and subsequent development of prehepatic portal hypertension.

Perioperative bleeding may occur because of profound coagulopathy and thrombocytopenia that many patients have pretransplantation as well as dilutional effects of intraoperative fluid administration. Bleeding should abate as the function of the allograft returns postoperatively. In addition, patients may return to the pediatric intensive care unit on heparin infusions to prophylactically maintain patency of the hepatic artery and portal vein. Monitoring surgical drain output is critical to detect postoperative bleeding and bile leakage. Additionally, monitoring of the hemoglobin is important as an indirect sign of bleeding. Worsening coagulopathy suggests hepatic dysfunction, sepsis with DIC, or unrecognized internal bleeding and requires rapid, aggressive diagnosis and treatment of the underlying cause.

Early biliary complications include biliary anastomosis dehiscence and bile leaks from the cut surface of the liver. Approximately 5% to 15% of patients experience biliary complications within the first 30 days, and up to 25% or more will experience this complication in long-term follow-up.[65] Early bile leaks may be diagnosed by the appearance of bile in the abdominal drains, by nuclear scan, or by transhepatic contrast studies. Cut surface leaks from minor biliary radicals may resolve spontaneously, but leaks from the biliary anastomosis or from larger cut surface ducts require percutaneous transhepatic cholangiogram (PTC) by interventional radiology, endoscopic retrograde cholangiopancreatography (ERCP), or surgical exploration. Late biliary complications include isolated anastomotic strictures or diffuse stricturing secondary to ischemic cholangiopathy. Isolated strictures can be managed usually by PTC or ERCP with dilation and temporary stenting, but diffuse cholangiopathy frequently progresses to biliary cirrhosis in the allograft.

After intraabdominal surgery, altered gut may predispose to bacterial translocation or infection may occur, particularly in the open abdomen, by more

directed routes. Any intraabdominal fluid collection secondary to bile leak, hematoma, or ascites may become infected. Serial examinations and imaging should be performed during the postoperative period to monitor for signs of abscess or fluid collection. Percutaneous drainage or surgical abdominal washout may be required.

Postoperative Management

Early recognition of complications and prompt intervention will offer the best chance to rescue the graft and the patient. Close and rapid communication between the PICU team caring for the postoperative transplant patient and the surgical and hepatology teams are crucial. Joint rounding with all teams caring for the patient can facilitate optimal communication during the critical postoperative period.

Fluid Management/Nutrition

The goal of fluid management is to preserve graft perfusion without fluid overload. Albumin should be monitored carefully and crystalloids should be given cautiously to avoid fluid overload and anasarca. In the early postoperative period, fluid balance should be calculated on an hourly basis rather than awaiting 12 or 24 hour totals. Initially the goal is to maintain an even to slightly positive fluid balance, and after about 48 hours postoperatively, when fluid begins to be mobilized from the tissues, diuresis can be expected. Central venous pressure monitoring is often helpful in assessing fluid needs.

Sedation/Pain Relief/Ventilation

Although it is important to manage postoperative pain, oversedation is a risk and should be avoided. The use of opioids demands judicious attention due to their risk for prolonging the need for ventilator support and slowing gastrointestinal motility and thus fluid mobilization from the abdominal compartment. Delirium from a prolonged ICU stay should not be confused with poor pain control. One aim of immediate posttransplant care is to wean the patient off of ventilator support as soon as it is feasible to do so. Increasingly extubation occurs in the operating room at the end of surgery or within the first hour or two of transfer to PICU. Prolonged ventilator support is associated with increased complications, prolonged ICU stay, and delayed discharge from the hospital.

Immunosuppression

Induction immunosuppression with either an antithymocyte globulin or an anti-IL2 antibody is used in about 40% of programs in the United States.[67] The mainstay of maintenance immunosuppression is the calcineurin inhibitor, tacrolimus with or without corticosteroids. Use of cyclosporine at least in liver transplantation is now mostly historical. The antimetabolite mycophenolate mofetil has replaced the use of azathioprine in centers that routinely utilize adjunctive therapy.

Infection Prophylaxis

During the perioperative period, prophylactic antibiotics are commonly used for 24 or 48 hours; the preference of antibiotic is program specific. Fluconazole may be used as fungal prophylaxis in high-risk situations, although for routine cases enteral

nystatin suffices. Specific prophylaxis for *Pneumocystis jirovecii* with Bactrim is standard once enteral medications are tolerated. Cytomegalovirus (CMV) prophylaxis either universally or for selected patients depending on donor and recipient CMV serologic status is initiated with IV ganciclovir, graduating later to oral valganciclovir.

Drains and Intravascular Access

Typically vascular access consists of two arterials catheters to facilitate monitoring blood pressure and blood draws, one central line usually internal jugular, a peripherally inserted central catheter (PICC), and peripheral intravenous catheters as needed. Large-bore nasogastric tubes are used for gastric decompression and a Foley catheter for accurately quantifying urine output. Surgical abdominal drains are usually in place upon return from the operating room primarily to monitor for intraabdominal bleeding or bile leak. Given the multitude of tubes and vascular access, the documentation of inputs and outputs is essential to reliably assess fluid balance.

Complications

Infection

Sepsis continues to be a major cause of morbidity in liver transplant recipients.[68] The presence of arterial thrombosis or biliary leak significantly increases the risk of infection as well as abscess formation. Patients having undergone previous abdominal surgery and those who have received pretransplant corticosteroid therapy are at an increased risk for postoperative infection. A high index of suspicion for postoperative infection in the immunosuppressed patient should be maintained with early surveillance cultures and the initiation of antibiotic, antifungal, and antiviral (CMV) treatments as indicated by the patient and donor status. Young children are at particular risk for CMV and Epstein-Barr virus infections because the majority are naive to these viruses at the time of transplantation. Donor lymphocytes in the graft are a frequent source of primary infection for these viruses. Monitoring active viral replication by polymerase chain reaction can be a useful tool to assist in preemptive management.[68]

Rejection

Data from the SPLIT Registry suggest that rejection occurs at least once in 46% of pediatric patients who require liver transplantation.[68] Laboratory findings suggestive of rejection include elevation in AST, ALT, and gamma-glutamyltransferase (GGT) followed by elevations in bilirubin in more severe cases. Liver biopsy is important to confirm the diagnosis of acute rejection and distinguish patients with viral infection, biliary obstruction, or graft ischemia who may have a similar clinical presentation. Early detection of rejection allows the initiation of intensified immunosuppression to reverse the process and minimize graft injury and loss. A short course of high-dose corticosteroids is the usual response to an episode of rejection, although more severe grades of rejection may necessitate the use of antithymocyte globulin.

Hypertension

The majority of liver transplantation patients will receive a calcineurin inhibitor and corticosteroids, setting the stage for postoperative hypertension with or without deterioration in biochemical renal function. Some degree of postoperative hypertension is seen in 70% to 80% of pediatric recipients. Hypertension is treated initially with calcium channel blockers but usually resolves over the first few weeks after transplantation. Angiotensin-converting enzyme (ACE) inhibitors have been suggested to offer protection against ongoing calcineurin-induced renal injury but should not be used early after transplant because of the associated risks of hyperkalemia and renal dysfunction.

Other Complications

Each of the immunosuppressant agents in common use has potential undesirable side effects.[69] The most common issues are listed in Table 99.7. Diabetes is relatively common in adult patients receiving tacrolimus with a prevalence of 25% at 3 months posttransplant, but this complication is uncommon in young children. Hyperglycemia in the immediate postoperative period can be controlled by insulin infusion and should not limit the clinician's ability to deliver adequate caloric intake.[70] Cyclosporine and tacrolimus-related encephalopathy and seizures occur in 11% and 8% of patients, respectively, with the most common onset in the first 2 weeks after transplantation. Both can be managed by reducing or eliminating the calcineurin inhibitor exposure. Seizure control will frequently require short-term treatment with antiepileptic medications.[71]

TABLE 99.7

Adverse Effects of Immunosuppression Medication

Agent	Adverse Effect
Tacrolimus	Hypertension, headache, infection, seizures, hyperglycemia, insulin resistance/diabetes, renal failure, PTLD, cardiomyopathy
Cyclosporine	Hypertension, infection, seizures, hyperglycemia, renal failure, hirsutism, gingival hyperplasia, PTLD
Sirolimus	Hypercholesterolemia, infection, edema, poor wound healing, PTLD
Corticosteroids	Hypertension, increased appetite, Cushing syndrome, acne, gastritis, poor wound healing, osteoporosis, poor linear growth
Mycophenolate	Intestinal hypermotility, abdominal cramping, diarrhea, infection, leukopenia, thrombocytopenia

PTLD, posttransplant lymphoproliferative disease.

Outcomes

Patient and graft survival rates have risen dramatically since the early attempts at liver transplantation. In modern cohorts, infants, children, and adolescents transplanted at experienced centers can expect 1-year survival rates in excess of 95%, with graft survival rates above 90%[72] (Fig. 99.3). The poorest survival has been seen for malignant tumors, mostly hepatoblastoma, and acute liver failure. Studies of Pediatric Liver Transplantation (SPLIT) data identify the occurrence of postoperative complications, especially reoperation, as the major risk factor for morbidity and graft loss.[72] Late-stage complications resulting in graft loss include chronic rejection, biliary cirrhosis, and posttransplant lymphoproliferative disease.

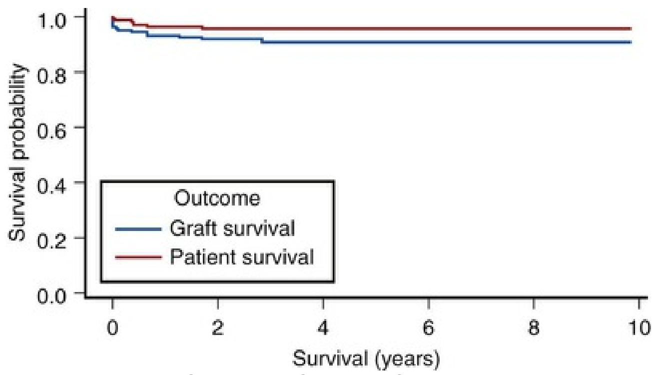

FIG. 99.3 Kaplan-Meier Survival Curve of 10-year experience of patient and graft at a single pediatric transplant center (Seattle Children's Hospital in Seattle, Washington, from 2004 to 2014 from 138 patients).

Children who receive liver transplantations may exhibit growth failure. This is more likely to affect those with cirrhosis and chronic liver disease as their indication for transplantation rather than those with acute liver failure. Nutritional status pretransplant somewhat predicts growth posttransplant. Catch-up growth may be observed for several years after transplant, although in those with stunted pretransplant growth, final adult height is often less than ideal.[73] Of note, a SPLIT study of quality of life in 800 liver transplant recipients reported that psychosocial function such as school function was affected more than physical function, with data similar to that for children with other chronic medical conditions.[74] Behavioral disturbances, anxiety, and depression along with posttraumatic stress disorder can appear posttransplant, and patients should be systematically evaluated for these conditions in addition to medical management during the posttransplant follow-up.

Indications for retransplantation include vascular complications (which account for a significant proportion early in the postoperative period), liver fibrosis, cholestasis, and chronic graft failures (which account for the majority of the late graft failures). Patient and graft survivals after retransplantation are approximately 10% less than survival rates after primary transplantation. A shorter time frame from primary transplantation to retransplantation has been reported to result in a higher likelihood of morbidity and mortality, but this has not been a consistent finding in all analyses.[75]

CHAPTER 100

Acute Abdomen

Robert Sawin, Derya Caglar

PEARLS

- The abdomen is both a primary source of disease conditions that requires care in the intensive care unit (ICU) and, frequently, a secondary source of additional pathophysiology for children in the ICU being treated for other conditions.
- In either case, early recognition of these conditions and the judicious use of medical and surgical intervention can be key to a successful outcome in critically ill children with abdominal disease or injury.

Anatomic and Physiologic Considerations

Peritoneum

The peritoneum provides a protective environment for the intraabdominal organs and, because of its marked sensitivity, a valuable window for the examining health care provider. It is composed of a single layer of mesothelial cells lining the abdominal cavity along the abdominal wall (the parietal peritoneum) and the intraabdominal viscera (the visceral peritoneum). The space between these is the peritoneal cavity. Beneath the mesothelium is a submesothelial layer of extracellular matrix, capillaries, and lymphatics.[1] The peritoneum's sensitivity to inflammation, ischemia, and necrosis is mediated by the fluid in the peritoneum that contains macrophages and other leukocytes.[2] Thus, with a focus of inflammation anywhere in the peritoneal cavity, these leukocytes release inflammatory mediators, often resulting initially in poorly localized, generalized pain. With irritation of the peritoneum associated with early appendicitis, for example, the patient interprets the inflammation as periumbilical pain. This is related to the embryologic development along dermatomes. As more inflammatory cytokines are secreted throughout the peritoneal cavity, the pain becomes more generalized and will eventually result in spasm of the overlying muscles of the abdominal wall, interpreted by the examiner as guarding.

Pain in the gastrointestinal tract is mainly limited to conditions that result in distention of the organ. Inflammation or irritation of the mucosa is generally not the cause of pain, except in the stomach. Disease states that result in full-thickness

inflammation of the bowel wall, however, can stimulate the visceral peritoneum, inciting the release of leukocytic and tissue macrophage–derived inflammatory mediators and resulting in pain. Patients who are receiving drugs such as corticosteroids, which blunt the immune response, have reduced production of these peritoneal inflammatory mediators and consequently can have deceptively little pain despite a significant intraabdominal disease. As in other parts of the body, ischemia associated with any abdominal condition results in severe pain, often out of proportion to what is detected on physical examination.

Visceral Blood Flow

The regulation of visceral blood flow is a tightly controlled balance of neural, humoral, paracrine, and metabolic factors.[3] In the gut, enteral feeding increases the blood flow and the metabolic demands on the intestinal mucosa. Some of these effects are directly related to the nutrients in the intestinal lumen, whereas others are dependent on the enteric nervous system and the associated reflexes, on gastrointestinal hormones, and on gastrointestinal vasoactive mediators such as adenosine, endothelin-1, and nitric oxide.[4] In pathologic states such as sepsis alone or shock, whether from sepsis, hemorrhage, or cardiac failure, visceral blood flow is reduced, and this can lead to ischemia of the intestinal mucosa and submucosa. Even with restoration of blood pressure and cardiac output following treatment of shock, microvascular perfusion of the intestine may remain impaired, resulting in mucosal ischemia and persistent lactate production.

Such ischemia can lead to altered integrity of the mucosal barriers to bacteria and other pathogens, thus increasing the entry of endotoxins into the splanchnic venous and lymphatic systems. These pathogens can fuel the inflammatory response. This finding has fostered the theory of the gut as a central organ of sepsis or multisystem organ failure (see also Chapter 112).[5] Whether the translocation of bacteria or endotoxin from gut lumen to splanchnic drainage is the chicken or the egg can be debated; regardless, this perturbation of intestinal blood flow contributes to the pathophysiology of shock and sepsis.

Other conditions in the ICU can affect splanchnic blood flow, especially mechanical ventilation with high inspiratory pressures, high positive end-expiratory pressure (PEEP), or high tidal volumes.[6,7]

Physical Exam of the Abdomen

One should always start the examination of the child by assessing vital signs. Fever is common in patients presenting with significant abdominal disease, but it may not always present early in the disease process. Tachycardia is seen with fever, pain, or anxiety but is also a sensitive indicator of serious underlying illness, often seen in patients with early, compensated shock. Hypotension may indicate a decompensated patient who needs immediate attention and intervention for likely sepsis.

The examination of a child's abdomen should begin with keen observation, patience, and sensitivity to the patient's fears and the parents' anxiety. One should first notice the child's position and demeanor. Children with peritonitis do not move or writhe about the bed, as this only worsens their pain. They will remain quite still

and avoid movement or any rapid changes in position. A child with visceral ischemia that has not progressed to peritonitis may be actively seeking a more comfortable position with multiple positional adjustments.

The abdomen should initially be evaluated for any skin changes that can give clues to the underlying process. Bruises or patterned abrasions and petechiae can indicate trauma with significant underlying organ lacerations or blood loss. Seat belt restraints can often leave a significant lesion on a child's chest and abdomen after a motor vehicle accident and should prompt further evaluation for intraabdominal injury. In the absence of reported trauma, the provider must consider nonaccidental trauma in the differential diagnosis, particularly in very young, nonverbal children. Grey Turner sign is significant bruising in the flanks, indicates significant retroperitoneal bruising, and is often associated with severe pancreatitis or pancreatic necrosis. Bruising around the umbilicus, Cullen sign, is also an indicator of significant intraabdominal bleeding and pancreatic disease.

Observation of the patient's facial expressions is important throughout the physical exam, as young children may not be able to express what they are feeling or simply are too anxious to give clear responses. Once the manual examination is to begin, the examiners should make certain that their hands and stethoscopes are warm. For the verbal child who has localized the pain to a specific portion of the abdomen, the examiners should start the palpation in the opposite quadrant. If palpation in one area causes referred pain in a different location (Rovsing sign), this is suggestive of localized peritonitis in the area of pain, classically seen in appendicitis but also seen in other localized abdominal conditions.

In generalized peritonitis, spasm of the rectus abdominis can be detected regardless of where the source of the inflammation is located. When rectus spasm is detected on one side of the abdomen, a comparison to the rectus on the other side is helpful; when both are in spasm, it could be a manifestation of guarding by an anxious child, and therefore distraction should be employed. Distraction can often be created by engaging in conversation with the verbal child or by using the warmed stethoscope to listen with light pressure over the area of the abdomen in question, followed by gradually increasing the pressure to elicit a response. Asking the child to take a deep breath and blow it all the way out while feeling the rectus can overcome the spasm if it is due to voluntary guarding, while a child with peritonitis will fail to relax the rectus spasm.

Testing for rebound tenderness is only valuable in older children and should be avoided in children younger than adolescence as it is too startling and thus has a high false-positive rate. Shaking the bed, asking the child to cough, or gently grabbing the hips and moving them from side to side will cause a painful response in conditions with peritonitis and is much less threatening to younger children. As mentioned earlier, pain out of proportion to the findings on physical exam in an ICU patient suggests ischemia, independent of the location in the body. Bowel sounds are highly variable, and their assessment is not usually useful in the intensive care unit patient.

Significant abdominal distention may also indicate considerable underlying illness. On the other hand, abdominal distention can make the physical exam more challenging. Differentiation between apparent tenderness from distention versus peritonitis requires patience and gentle palpation. Assessing the rectus muscles for spasm may facilitate the diagnosis of peritonitis. Distention from hepatomegaly or

splenomegaly can be due to end-stage liver disease, malignancy, or masses. Fluid in the abdomen could indicate significant blood loss requiring immediate attention and resuscitation. Ascites with abdominal pain may be an indicator of spontaneous bacterial peritonitis, particularly in patients with end-stage renal or liver disease.

Medications can interfere with the reliability of the physical exam of the abdomen. As mentioned, steroids can blunt an inflammatory response in the peritoneum and lead to decreased pain sensation despite a significant intraabdominal disease process. Patients receiving opiates may have a diminished response to painful stimuli; however, significant intraperitoneal pathology can still be ascertained by careful observation and examination. Patients who are receiving paralytic drugs are particularly challenging because the rectus abdominis spasm associated with peritonitis may be substantially decreased. Observation of the face, heart rate, or blood pressure can still be valuable, especially by comparing these findings during examination to other areas of the body. Just as in the nonsedated, non-ICU patient, beginning the exam on another portion of the body gives the examiner a baseline for comparison.

Laboratory Tests

Assessment of possible intraabdominal conditions should include blood and serum tests that measure inflammation, acid-base abnormalities, possible coagulopathy, and those focused on suspected involved organs. The leukocyte count and differential, hematocrit, and platelet counts should always be checked for patients with suspected abdominal disease. Leukocytosis, especially with an increased percentage of neutrophils or immature forms, should raise one's concern about an infectious process. Neutropenia suggests a more severe infection or a suppression of the patient's bone marrow from medications or from the infection; such a situation might make clearance of a bacterial infection more difficult. Similarly, both an increased and decreased platelet count can indicate an intraabdominal infection. Serial declines in the platelet count are particularly suggestive of a continuing inflammatory consumption seen in conditions such a necrotizing enterocolitis. Hematocrits must be followed in any child in the ICU because they can demonstrate intraabdominal bleeding or hemolysis related to disseminated intravascular coagulopathy (DIC). Other coagulation tests should be considered, especially in children with severe infections or those with liver dysfunction. In such situations the prothrombin time (PT) partial thromboplastin time (PTT), D-dimers, and fibrin split products are helpful to characterize and monitor the coagulopathy.

Abnormalities of acid-base balance should be monitored regularly in a child hospitalized in the ICU with an abdominal disease process. The source of increased acid can either be an overproduction, such as ongoing lactate generation by ischemic bowel, or decreased acid clearance by the liver or kidneys in conditions associated with shock and decreased visceral blood flow. Lactate is a sensitive measure of intestinal ischemia, especially when monitored serially for trends.[8] Arterial blood samples are more reliable than venous samples in that measurement. Hyperlactemia is not specific to intestinal ischemia and can be associated with any tissue necrosis or underperfusion of organs. Elevated serum lactate is also associated with a worse prognosis in patients with sepsis, and the normalization of lactate levels after resuscitation is associated with improved prognosis in patients with sepsis.[9]

Liver function tests, more accurately termed liver injury tests, include transaminases (alanine transaminase [ALT] and aspartate transaminase [AST]), bilirubin, and gamma glutamine transferase (GGT). These can be elevated with trauma to the liver, active hepatic inflammation, hepatic ischemia, or obstruction of the hepatic venous outflow, known as Budd Chiari syndrome. The latter can result in extremely elevated transaminase levels. Elevation of the GGT without a significant rise in the transaminase suggests a biliary condition such as common bile duct obstruction or cholecystitis.

Amylase is a valuable diagnostic test for children with abdominal pain or unexplained intraabdominal sepsis, as hyperamylasemia can indicate pancreatitis. Elevated amylase is not specific to pancreatic insults and can be elevated with head trauma, decreased renal clearance, and intestinal obstruction. Serum lipase can be an additive test to the assessment of the pancreas. It tends to be more specific to the pancreas but can be mildly elevated in intestinal obstruction as well. When both amylase and lipase are markedly elevated, pancreatitis is most likely. Children with a past history of severe or chronic pancreatitis might not have marked elevations, so the level of the enzyme does not always correlate with the severity of the disease.

Imaging Options

The reliability of abdominal exam is subjective, highly variable, and may depend on the experience of the observer, the fluctuating status of the patient, his or her medications, the patient's level of anxiety, and many other factors. Consequently, most ICU providers use imaging studies to ascertain whether intraabdominal pathology warrants intervention. For reasons of resource efficiency as well as considerations about the potential risks of ionizing radiation and patient comfort/safety, prudence needs to be exercised before ordering expensive, potentially obfuscating data from imaging studies. The following factors should always be evaluated before performing each study:

1. Specifically, what is one looking for—that is, what is the differential diagnosis?

2. How reliably will this study rule in or rule out those diagnoses—that is, what is the specificity and sensitivity of the study?

3. Will the results of this study change the management—that is, will a negative result prompt the termination of a drug regimen or life-supporting technology, and will a positive study necessitate surgical intervention or initiation of a new therapy?

4. Are the risks—such as ionizing radiation, transportation of a heavily medicated or unstable patient from the ICU to the radiology suite, the administration of intravenous contrast, and so on—offset by the value of the study?

Ultrasonography

Ultrasonography has several advantages over other imaging studies, most notably its portability, which obviates the need for moving the patient, and its lack of ionizing radiation exposure. In addition, the use of Doppler modality permits the

assessment of visceral blood flow to kidneys, pelvic organs, and the gastrointestinal tract.

When the relative positions of the mesenteric vein and artery can be accurately determined, an abnormal orientation suggests an increased risk of malrotation, even without midgut volvulus.[10] The presence of a whirlpool sign can be diagnostic of malrotation with midgut volvulus.[11] Neither finding, however, is sensitive enough to exclude the diagnosis of malrotation, thus necessitating an upper gastrointestinal contrast study to clearly determine the position of the duodenal-jejunal junction.[12] Assessments of gallbladder wall thickening suggestive of acalculous cholecystitis or biliary tree dilation are particularly accurate. Intraabdominal and pelvic fluid collections can be identified, making ultrasound useful in the setting of traumatic injury or suspected intraabdominal abscess. It can be used as an adjunct to guide fluid drainage either surgically or percutaneously.

The use of ultrasound is limited in patients with bowel obstruction or severe paralytic ileus as intestinal distention creates ultrasonic distortion, minimizing the value of this imaging modality. Accuracy of images is also highly dependent on having a skilled and experienced technician.

Abdominal Plain Radiographs

Plain radiographs of the abdomen can be revealing and also are portable, relatively inexpensive, involve small amounts of radiation, and require minimal patient movement. To be of greatest value, however, the abdominal radiograph should be done with the patient in at least two different positions, such as supine and upright, and ideally lateral decubitus as well. Cross-table laterals can also add value. These different views facilitate the identification of air-fluid levels suggestive of small bowel obstruction and the presence of pneumoperitoneum indicating likely visceral perforation. Pneumoperitoneum in a patient with high inspiratory pressures on a mechanical ventilator can sometimes be unrelated to abdominal pathology but rather a consequence of air dissecting through mediastinal and diaphragmatic tissue planes. Other plain radiograph findings suggestive of intestinal disease include thumb printing, pneumatosis intestinalis, and portal venous gas.

Computed Tomography

Abdominal CT scans are accurate, fairly rapid, and can be used to guide interventional procedures such as percutaneous biopsies or drainage of intraabdominal fluid collections. Except in institutions where CT scans are located in the ICU or those that have mobile CT units, patients must be transported to access imaging with this modality. That requirement can be a significant challenge with children who are ventilated or hemodynamically unstable. In addition to the transport challenges, the radiation exposure of a CT scan may pose a risk for developing malignancies later in life, especially for children who receive serial radiographs.[13] That risk can be reduced by using directed scans (ie, limiting the scan to the portion of the abdomen in question). Other risks include the administration of intravenous contrast material that can cause anaphylaxis in those who are allergic or renal injury especially in those who might already be hypovolemic or receiving nephrotoxic drugs.[14] That risk can be minimized as well by using nonionic contrast

materials or with the administration of sodium bicarbonate and *N*-acetylcysteine prior to the administration of the IV contrast. Administration of enteral contrast can result in aspiration if there is intestinal obstruction or delayed gastric emptying with vomiting or gastroesophageal reflux.

The abdominal CT scan can be effective at identifying the condition of all the intraabdominal organs and the retroperitoneal spaces. It is being used with increasing success to assess for bowel obstruction. Identification of fluid collections and their characteristics can help ascertain whether blood, bile, or pus is present and whether it can be drained percutaneously. To make certain that nonopacification of fluid-filled loops of bowel is not misconstrued for pathologic collections of fluid, enteral contrast should be given as long as no contraindications exist. With IV contrast and carefully timed image capture, conclusions about organ perfusion can be assessed as well. Colonic and intestinal ischemia, necrotizing pancreatitis, and decreased renal perfusion can all be seen reliably.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) of the abdomen can be valuable, especially as the risks of radiation can be obviated, but the logistical challenges of moving an ICU patient to the MRI suite are similar to those mentioned earlier for CT scans. The added challenges posed by MRI include the slower speed of the image capture, which interferes with accessing the unstable patient for interventions, as well as the restrictions for certain MRI-incompatible ICU equipment to be in the MRI scanning room. Despite these issues, MRI enterography and cholangiography are now capable of generating revealing images of the gastrointestinal and hepatobiliary tracts.[15] Thus, if the value of the images can offset the risks of transporting a sick child to the MRI suite, it should be considered.

Abdominal Conditions Requiring Treatment in the Intensive Care Unit

Perforated Viscera

Children with perforation of the gastrointestinal tract will frequently require either preoperative resuscitation or postoperative stabilization in the ICU. The most common condition resulting in perforation is appendicitis. Although perforated appendicitis is common, occurring in 30% to 50% of children who present to children's hospitals with appendicitis,[16] it is unusual for it to result in serious intraabdominal sepsis. Nevertheless, deaths do still occur in such children, related most often to septic shock with cardiovascular collapse or severe acute respiratory distress syndrome (ARDS).

Other sites of perforation in the gastrointestinal tract include gastric or proximal intestinal perforation from severe gastritis, peptic ulcer disease, gastric ischemia, or following manipulations such as insertion of gastric tubes or transpyloric feeding tubes.[17] In children with chronic gastrostomies, accidental dislodgements or manipulations of the gastrostomy site can result in separation of the stomach from the abdominal wall, leading to spillage of gastric contents into the peritoneal cavity. Because the acidic gastric pH results in lower bacterial counts, such perforations do

not usually result in serious intraabdominal sepsis. However, chronically hospitalized children or children with gastroesophageal reflux on chronic acid suppression therapies may be colonized with resistant bacterial or fungal organisms such as *Candida* species that can lead to serious septic consequences.

Ingested foreign bodies can lead to perforation anywhere in the gastrointestinal tract, with common items being sharp materials such as pins or nails, fish bones, disc batteries, and magnets.[18] Magnet ingestion incidents, in particular, have dramatically risen since the early 2000s and have led to serious injury and death. If more than one magnet is ingested, the magnets can pinch loops of bowel and lead to ischemia, necrosis, perforation, and death.[18–20]

Trauma can also result in perforation. The lap portion of a seat belt can cause an abrupt and significant increase in intraabdominal pressures during motor vehicle accidents. Patients may sustain intestinal perforation, organ lacerations, or significant intraabdominal hematomas requiring ICU care. Abdominal injury is the second most common cause of death in abused children after head injury. A punch or kick can compress the small bowel against the vertebral column causing a jejunal perforation. So characteristic is this mechanism that the intraoperative finding of a jejunal perforation in the absence of a known trauma history should prompt an evaluation by the hospital's child abuse team.[21] Sports injuries, from skateboarding to all-terrain vehicle (ATV) use, can all lead to significant injury requiring resuscitation.[22]

Ischemia

Volvulus of a loop of small intestine can occur when a segment of bowel, typically distal ileum, becomes entrapped beneath an omphalomesenteric remnant. This particular lesion can be difficult to diagnose, as neither contrast enema radiographs nor antegrade upper gastrointestinal contrast studies are likely to reach the involved area of volvulus. In addition, these children will often not have impressive physical exam findings until the bowel has become ischemic. At that point, systemic sepsis can occur rapidly. Similar pathophysiology can develop from a twist of bowel within an internal hernia.

In children with intestinal malrotation, the entire intestine supplied by the superior mesenteric artery (ie, from jejunum to right transverse colon) can twist, resulting in midgut volvulus. In a somewhat similar manner, the colon alone can twist when there is sufficient redundancy in the mesocolon, typically in the cecum or the sigmoid colon. In any of these situations with intestinal and mesenteric twisting, the resultant venous congestion can compromise the capillary inflow to the bowel wall, ultimately leading to irreversible ischemia if the bowel is not untwisted promptly. With venous congestion as an early component of these obstructive volvulus conditions, there may be less release of lactate into systemic circulation, potentially leading to a falsely reassuring normal lactate level despite significant intestinal ischemia.

In the pediatric ICU, another cause of intestinal ischemia is low cardiac output or hypoxemia. Children with congenital heart disease, particularly those with single ventricle physiology or severe cyanotic heart disease, can develop mucosal ischemia following cardiac surgery, manifested as pneumatosis intestinalis on radiographs, bloody stool, metabolic acidosis with elevated serum lactate, and sepsis. Children on

potent vasoactive pressors, such as epinephrine or norepinephrine, and those receiving extracorporeal support can develop ischemia as well. This is a variant of necrotizing enterocolitis (NEC) and can involve the entire small intestine and less commonly the colon. If the diminished cardiac output or hypoxemia is corrected and the ischemia is limited to the mucosa, surgical treatment may be avoided. Resection is necessary if the acidosis or systemic perturbations are refractory or if perforation results. Unfortunately, as this disease can involve the entire gut, the utility of resection may be limited.

Other causes of intestinal ischemia include small bowel obstruction, usually from adhesions following previous laparotomies or, less commonly, related to incarcerated inguinal hernias. If the bowel becomes sufficiently distended, the intraluminal pressure can exceed the intramural perfusion pressure of the microcirculation, resulting in ischemia. Other less common causes of intestinal ischemia include conditions that alter the microcirculation of the bowel wall such as vasculitis or hemolytic uremic syndrome.

The systemic physiologic insult of intestinal ischemia is usually proportional to the degree of ischemic tissue. Thus midgut volvulus or total intestinal involvement with NEC can be the most catastrophic of these disease states acutely and can have the most devastating long-term consequences with short bowel syndrome and intestinal failure a common consequence if the ischemia is irreversible.

Neutropenic Enterocolitis

Children who have significant neutropenia, whether drug induced from chemotherapy for malignant diseases or as a primary disease, may develop inflammation of the intestinal tract. The most common location is the right colon. Historically, this has been termed *typhlitis,* but more accurately it is labeled neutropenic enterocolitis, as it can affect other portions of the intestinal tract as well. It may be preceded by mucositis that permits the intestinal bacteria to invade the bowel wall. Affected children exhibit fever, abdominal pain and tenderness, abdominal distention, ileus or diarrhea, radiographic signs of inflammation, and sometimes hemodynamic instability. The diagnosis is made best by CT scan or ultrasound.[23] Surgical treatment is reserved for patients with peritonitis or hemodynamic instability after appropriate resuscitation.

Pancreatitis

Severe pancreatitis can require intensive care in children. Etiologies for the pancreatitis are most often idiopathic in children, but anatomic causes such as gallstones, pancreatic trauma, or pancreas divisum can also be responsible. Drugs and hemolytic uremic syndrome can be unusual causes of severe pancreatitis.[24] In severe cases, pancreatitis can lead to significant third space fluid losses, pleural effusions, retroperitoneal hemorrhage, abscess formation, and hypocalcemia. Necrotizing pancreatitis, though rare in children, can require repeated surgical debridement to eradicate the ongoing source of sepsis.

Hemorrhage

Intraabdominal hemorrhage can result from trauma or following surgical procedures or manipulations. In blunt trauma, the spleen is the most commonly injured abdominal organ. To avoid the risk of overwhelming postsplenectomy infection (OPSI), nonoperative management is attempted as long as hemodynamic stability can be maintained. Hospitalization in the PICU with strict bed rest is indicated when the splenic injury is grade IV or V or if there are other significant injuries.[25] The risk of delayed splenic rupture following nonoperative management is extremely low. If surgery is necessary, attempts to salvage the spleen with splenorrhaphy are important. Before surgery, if time permits, the child should be immunized for encapsulated bacterial organisms including *Haemophilus influenza, Streptococcus pneumoniae,* and meningococcus.

The liver is also a commonly injured organ in blunt abdominal trauma, and it too can usually be managed nonoperatively. The development of hemobilia several weeks after nonoperative management of a hepatic laceration is uncommon, but when it occurs it can result in significant gastrointestinal bleeding. This can usually be managed with arteriographic embolization or endoscopic biliary stent placement,[26] but it sometimes requires resection of the involved hepatic segment or lobe (see also Chapter 121).

Other Specific Conditions

Cholecystitis

Gallstones are increasingly common in children, perhaps because of the increased use of parenteral nutrition with its associated risk of cholestasis or the increasing prevalence of childhood obesity.[27] Gallstones can result in cholecystitis, biliary obstruction, or pancreatitis that can complicate an intensive care unit course for a child. Acalculous cholecystitis can be seen in children who are hospitalized in the ICU, particularly those who are receiving large doses of opiates that lead to biliary dyskinesia or those who have decreased perfusion of the abdominal organs because of hypotension. Acalculous cholecystitis can be associated with a significant systemic inflammatory response and should be considered as a source of unexplained sepsis in a child. Ultrasonographic and CT scan findings of a dilated gallbladder with a thickened gallbladder wall and pericholecystic fluid are diagnostic, although a radionuclide study such as a hepatobiliary iminodiacetic acid (HIDA) scan is the most accurate functional imaging study.

Empiric antibiotic coverage for common biliary pathogens such as gram-negative organisms like Klebsiella, pseudomonas, or *E. coli* should be started immediately. Cholecystectomy would be definitive therapy. In critically ill children who might not tolerate a trip to the operating room, percutaneous drainage of the gallbladder done by ultrasound guidance in the ICU can be an effective temporizing procedure.

Spontaneous Bacterial Peritonitis

Spontaneous bacterial peritonitis (SBP) is an acute bacterial infection of ascitic abdominal fluid that may present with fever, abdominal pain, altered mental status, or persistent vomiting.[28] Enteric organisms have traditionally been isolated from more than 90% of infected ascites fluid in spontaneous bacterial peritonitis,

suggesting that the gastrointestinal (GI) tract is the source of bacterial contamination. This is thought to be due to direct transmural migration of bacteria from an intestinal or hollow organ lumen. An alternative proposed mechanism for bacterial inoculation of ascites is via hematogenous transmission in conjunction with an impaired immune system. The debate continues and the exact mechanism of bacterial displacement from the GI tract into ascites fluid remains controversial. If suspected, broad-spectrum antibiotics should be initiated to cover GI flora until culture results can guide therapy further.

Abdominal Compartment Syndrome

Intraabdominal hypertension (IAH) is defined as intraabdominal pressure (IAP) that is >12 mm Hg. Although this is relatively uncommon in pediatric ICU patients, it can be associated with a high morbidity and mortality. If the IAP reaches a point where perfusion to intraabdominal organs is compromised, a constellation of organ dysfunctions may occur including renal insufficiency, intestinal ischemia, hepatic dysfunction, elevated diaphragms, and respiratory insufficiency.[29–31] This constellation is termed *abdominal compartment syndrome (ACS).* Risk factors for ACS include massive fluid resuscitation for any illness, intraabdominal hemorrhage, intraabdominal inflammation or infection from any cause, obesity, and tight abdominal wall closures following laparotomy. Like compartment syndrome in extremities, there is no absolute pressure to define the presence of ACS; the intravascular volume status, blood pressure, and systemic vascular resistance are all factors that can impact the perfusion pressure of the abdominal organs and minimize the effect of the IAP. An abdominal perfusion pressure (APP) can be calculated as the mean arterial pressure minus the IAP. If the APP is >60 mm Hg, a higher survival rate has been reported. The diagnosis of ACS is made when there is a sustained increased IAP in combination with signs of organ dysfunction such as decreased cardiac output, oliguria, and respiratory insufficiency. Other organ systems that can be affected by IAH include the reduction of portal and mesenteric venous flow, potentially leading to hepatic dysfunction and intestinal edema, and ischemia. In addition, the increased intrathoracic pressure that can result from the elevated diaphragms can raise intracranial pressure.

When signs of IAH are evident in the setting of abdominal distention, pressure measurements can be made using nasogastric tubes, rectal catheters, bladder catheters, and peritoneal drainage tubes such as peritoneal dialysis catheters. The most reliable and easily practical measurement can be obtained using a closed system of a Foley bladder catheter connected to a fluid column and a pressure measuring device such as a tube manometer or a pressure transducer. Ultrasound evaluation, including Doppler imaging of renal, portal, and mesenteric blood flow can be helpful in the assessment of end-organ perfusion, as well as estimating the intraabdominal venous pressure by assessing the caliber of the inferior vena cava (IVC). CT scan can also reveal poor perfusion of these organs and a flattened IVC, as well as increased abdominal girth, especially in the anterior to posterior dimension.

If the diagnosis of ACS is suspected, efforts to augment perfusion must be initiated. Avoid the reverse Trendelenburg or prone positions, as these can increase IAP. Effective decompression of the gastrointestinal tract is important and can be optimized by effective nasogastric tube drainage, the administration of prokinetic

medications, and colonic decompression by either enemas or colonoscopy. Supporting renal function is also important and includes liberal use of diuretics along with volume resuscitation. If these maneuvers have not improved the organ function, temporary decompression by insertion of an abdominal drain to decrease the amount of fluid in the abdomen may be necessary.[32] If this does not adequately decompress the IAH, laparotomy is necessary with placement of a sterile patch or silo that may provide sufficient compliance to reverse the ACS.

The morbidity of ACS is significant, with mortality rates of >50% reported, especially if treatment is delayed until multisystem organ failure develops. After decompression, and once resolution of any end-organ dysfunction occurs and after the underlying causes of the IAH have abated, delayed closure of the abdomen can be considered. Sometimes that closure will require abdominal wall reconstruction techniques such as skin flap closure without fascial repair or skin grafts. Primary or delayed primary fascial repair may be feasible, sometimes requiring separation and release of the muscle groups or insertion of prosthetic patches such as synthetic mesh, Gore-tex, or biological sheet materials that serve as a protein matrix for tissue ingrowth.

Intraabdominal Abscess

Intraabdominal abscesses are highly variable in presentation. Patients may present with significant abdominal pain, spiking fevers, prolonged ileus after a surgical procedure, or leukocytosis. Classic physical findings may be absent in a deep abscess, where the only clues may be persistent fevers, tachycardia, and mild persistent GI dysfunction. Postoperative analgesics and incisional pain frequently mask abdominal findings. In addition, antibiotic administration may mask abdominal tenderness, fever, and leukocytosis.

In patients with subphrenic abscesses, irritation of the diaphragm may lead to shoulder pain, persistent episodes of hiccups, or unexplained pleural effusions, atelectasis, or pneumonia. With pelvic abscesses, frequent urination, diarrhea, or tenesmus may occur. If these abscesses go unrecognized, patients may develop a significant septic response that can lead to multiple organ failure and death.

Intestine as a Source of Sepsis

The intestine is an organ endowed with large quantities of both lymphatic tissue and bacteria. Consequently, it can be a central organ in the systemic inflammatory response in children hospitalized in the ICU. The role of the gut's immune system is not fully understood but may play a key role in some intestinal inflammatory diseases such as Crohn disease. In addition, the interplay between the gut-associated lymphoid tissue (GALT) and the bacteria present in the bowel lumen is important in critical illness. The sick child with decreased visceral blood flow and under severe stress likely has alterations in the mucosal integrity of the intestine. That loss of integrity can lead to bacterial invasion of the bowel wall with subsequent entry of the bacteria/toxins into the lymphatic or portal venous circulation. Once in the circulation, these bacteria/toxins can trigger a severe systemic inflammatory response, even if the bacteria are not detectable as a bloodstream infection. Use of

enteral antibiotics to decrease potentially pathologic gut bacteria has proved effective in reducing intestinal sources of sepsis in some settings, whereas replacement of gut flora using probiotics or synbiotics has been employed with some success in others.[33]

Surgical Intervention

The decision to perform a laparotomy or laparoscopy in a pediatric ICU patient can be challenging. There are indeed times when a patient can be too sick to go to the operating room and other times when the patient is so sick that only an immediate operation will provide a chance for successful treatment.

With the possible exception of patients with continued intraabdominal hemorrhage or abdominal compartment syndrome, delaying operative treatment with time spent on preoperative resuscitation is often valuable. Induction of general anesthesia in a hypovolemic or acidotic patient with cardiogenic or septic shock can be dangerous. An understanding of the differential diagnosis can be most helpful in planning the appropriate antibiotic coverage and the timing of the surgical treatment. Most of the conditions that require laparotomy in ICU patients have an infectious component, and thus empiric broad-spectrum antibiotics should be administered early in the resuscitation. Depending on the disease, resuscitation and antibiotics alone may obviate the need for emergent laparotomy. Effective communication between the surgical team and ICU team is therefore essential. To optimize the timing of the operation, the surgical team should be ready to go immediately, once the preoperative resuscitation is sufficient. In situations where physical exam or radiographs do not provide localization, bedside imaging can help localize the disease. Image-guided drainage of localized infection may be a successful strategy in lieu of a full laparotomy with its incumbent risks,[34,35] or it may help to improve the physiology so that a definitive operation can be more safely performed after the condition has stabilized.

SECTION IX

Immunity and Infection

OUTLINE

CHAPTER 101

Innate Immune System

Samiran Ray, Rachel S. Agbeko, Mark J. Peters

PEARLS

- Innate immunity provides the front-line “ready-made” response to pathogen invasion.
- These same pathways are activated in response to other critical insults including trauma, hypoxic/ischemic injury, and bypass.
- Pattern recognition molecules recognize exogenous and endogenous molecular patterns.
- Therapeutic interventions in the ICU can have consequences on the innate immune response.

The immune system is a complex, sophisticated defense system that protects the body from danger. Danger may be intrinsic (eg, cancer) or extrinsic (eg, pathogenic organisms). The immune system provides constant surveillance to detect potential danger, identifies the nature of the threat, and then mounts a nullifying response. The immune system is also self-regulating: Once the threat is nullified, the response needs to be called off.

Traditionally a distinction is made between adaptive and innate immune responses. The adaptive immune system has been studied in the greater detail and is responsible for a **specific** response to individual pathogens. Adaptive immunity is a highly sophisticated process with many safety mechanisms to target responses at pathogens (or pathogen-infected cells) while leaving normal tissues alone. This sophistication and specificity take time to develop (of the order of days to weeks) and have many effector cells and molecules to deliver a coordinated response, including T and B lymphocytes and immunoglobulins. While the adaptive response is essential for health and in particular for the phenomenon of immunologic memory, it is not sufficient to address a sudden major bacteremia or widespread tissue injury—or even the thousands of minor bacterial inoculums all individuals experience during their lifetimes (eg, during teeth brushing). Bacterial growth is exponential under optimal conditions. *Neisseria meningitides* counts can double in 20 minutes. Given these threats, there is a need for a “ready-made” system that can act swiftly to neutralize external threats. This is called the innate immune system.

Innate immunity is phylogenetically conserved and found in nearly all

multicellular organisms; again, this contrasts with the adaptive immune system that is found in vertebrates only. In humans the innate immune system is largely present at birth, in contrast to the years it takes to build an adaptive immune repertoire. The hallmarks of the innate immune system are immediacy, promiscuousness, redundancy, and generality. Given that the adaptive immune system evolved in the presence of innate immunity, these systems do not operate in isolation from each other; rather, the innate immune system presents to and instructs the adaptive part of immunity.

Innate immunity is mediated through immune cells, such as tissue macrophages, neutrophils, and monocytes, but also cells that are primarily known for other functions: platelets and endothelial cells. Complex networks of circulating mediators including the complement cascade, collectins, defensins, and the coagulation cascade are integral parts of innate immunity. Recent work has highlighted apparent contributions from neurohumoral and autonomic nervous systems.

No critically ill child is admitted to the ICU without activation of its innate immune system. No intensivist can function adequately without a good working knowledge of innate immunity, as it is central to many of the clinical entities he or she faces on a day-to-day basis. Infection, trauma, ischemia-reperfusion, acute respiratory distress syndrome, and cardiopulmonary bypass sequelae are all largely mediated by the innate immune system.

This chapter provides a framework and outline of concepts in innate immunity that will help you understand some of the pathophysiologic processes central to pediatric critical care.

Components of Innate Immune System

An ideal first-line response to danger would be pervasive, prompt, effective, and calibrated. The required steps are recognition of a danger signal; dispatch of messengers to mount a response; mounting an effector response that neutralizes danger; and controlling the response to contain damage.

Innate Immune Stimulus—Danger Hypothesis

The traditional paradigm of the immune system suggests that it is programmed, through evolution and adaptation, to differentiate between self and nonself. In this view invading pathogens such as bacteria would be recognized as nonself and trigger an immune response, while newly replicating blood cells would not. However, this does not explain how animals can host entire microbiomes on their mucosal surfaces without inducing an immune response. Similarly, it does not explain how a developing fetus is protected from the maternal immune system.

The danger hypothesis suggests that the immune system does not simply detect self from nonself but instead detects danger or tissue damage. As the first line of defense, the innate immune system has to do this rapidly against an almost infinite number of pathogens or noxious molecules. This response is not learned, and it is conserved across phyla.

How does the immune system differentiate between endogenous and pathogenic molecules? The danger hypothesis suggests that it does not. The innate immune response is triggered by molecular patterns that are associated with pathogenic organisms or tissue damage, or both. These signals, known as **d**anger-**a**ssociated

molecular **p**atterns (DAMPs), are a diverse set of molecules (or parts of molecules, or polymeric components) that share recognizable common features, which identify them as pathogenic.[1] For example, nucleic acids or mitochondrial proteins released from their intracellular compartment during tissue damage or invading organisms are typical DAMPs. Similarly, hydrophobic protein moieties, or "hyppos," are also often hidden within tertiary and quaternary protein structures. When they are exposed, they become DAMPs and trigger an innate immune response.

When associated with pathogens, these molecular patterns signaling danger are known as **p**athogen-**a**ssociated **m**olecular **p**roteins (PAMPs). Lipopolysaccharide is an example of PAMPs within the bacterial cell wall, where the hydrophobic part of lipopolysaccharide is hidden. When released by pathogens, this becomes exposed and acts as a PAMP. All hyppos *can* be DAMPs including lipid particles and nucleic acids. Protein misfolding, damage, or binding to other molecules (eg, lipopolysaccharide-binding protein [LBP] binding to lipopolysaccharide) can lead to hyppos being exposed, and normally functional endogenous proteins may become DAMPs. That not all hyppos are always immunostimulatory may be down to the level of aggregation or quantity (evolved from quorum sensing used by eukaryotic colonies such as bacteria—a certain concentration of exposed hyppos will alert the colony of impending danger).[2]

DAMPs released following cell or tissue damage trigger responses from the innate immune system, which are similar to those produced by PAMPs.[3] These endogenous signals are known as "alarmins." High-mobility group protein B1 (HMGB-1) is one of the best described alarmins. In an intact cell, HMGB-1 is a histone-associated chromatin protein, involved in DNA structural modulation, thereby regulating transcription. However, following necrosis, the intranuclear HMGB-1 is released and recognized by receptors for advanced glycated endproducts (RAGE), which initiates an immune response aimed to contain damage. Cells have also evolved to release HGMB-1 in response to other signs of danger, which in the case of ischemia/reperfusion may lead to actively amplifying the immune response.[4]

Signal Recognition

Pattern recognition receptors (PRRs), a group of molecules with repeating sugars or specific amino acid motifs, recognize the typical molecular patterns of DAMPs. PRRs can be soluble circulating molecules, bound to cell surfaces, or intracellular. There is crossover between the types of PRRs—some PRRs such as CD14 can operate both as a cell surface–bound receptor but also in soluble form.

Circulating PRRs include sugar-recognizing collectins, ficolins, and small peptides called antimicrobial peptides. Mannose-binding lectin (MBL) is produced in the liver and activates the complement system after binding typical repeated sugar patterns on pathogen cell walls. Lower MBL levels increase risk of infection and the systemic inflammatory response in adults and children.[5] Interestingly, high levels of MBL expression are associated with preterm labor, while moderately low levels of MBL have been associated with better protection from mycobacteria infection and complement-associated inflammatory damage from certain infections such as meningococcal disease.[6,7]

Bacterial permeability increasing protein (BPI) is an antimicrobial protein. It acts against gram-negative bacteria by increasing cell wall permeability and has been investigated as a therapeutic agent in meningococcal sepsis in children. Although

there was no mortality benefit, there was a tendency toward a reduction in sequelae.[8]

Toll-like receptors (TLRs) are the best characterized group of membrane-bound PRRs. There are at least 10 related receptors in humans and 12 in mice (Table 101.1). TLRs are evolutionarily preserved from the worm *Caenorhabditis elegans* and strikingly homologous to Toll, a gene product essential to *Drosophila* immunity and dorsoventral patterning.[9]

TABLE 101.1

Toll-Like Receptor Family in Humans, Described by Pathogen-Associated Molecular Proteins (PAMPs), Organism, Alarmin, and Localization

PRR	PAMP	Organism	Alarmin	Location
TLR1-TLR2	Triacyl lipopolypeptide	Gram-negative bacteria Mycobacteria		Cell surface
TLR2	Porins Peptidoglycan Lipoarabinomannan Hemagglutinin protein tGPI-mutin	Neisseria Gram-positive bacteria Mycobacteria Measles Parasites	Hyaluronic acid HSP70 HMGB-1	Cell surface
TLR3	dsDNA	Viruses		Intracellular vesicles

Adapted from LaRue H, Ayari C, Bergeron A, et al. Toll-like receptors in urothelial cells—targets for cancer immunotherapy. Nat Rev Urol. 2013;10:537-545.

The TLR family can be divided into two subgroups depending on location. TLRs 1, 2, 4, 5, and 6 are bound to cell surfaces and recognize microbial membrane components. The remaining TLRs 3, 7, 8, and 9 are expressed in intracellular membrane-bound organelles and vesicles, such as the endoplasmic reticulum, endosomes, and lysosomes, where they typically recognize nucleic acids from intracellular pathogens.

TLR4 is the best described of the cell surface TLRs, given its central role in the pathogenicity of gram-negative septic shock as a key part of the lipopolysaccharide (LPS) recognition apparatus. In order to bind LPS, TLR4 forms a dimeric complex, in association with MD2. This complex formation exposes the binding site that recognizes LPS. LPS-binding protein (LBP) binds to LPS, which allows recognition by soluble CD14. CD14 is instrumental in delivering the LPS-bound complex to the TLR4/MD2 complex on the cell surface. TLR4 can also bind to the streptococcal toxin pneumolysin, respiratory syncytial virus (RSV) fusion protein, and paclitaxel, the chemotherapeutic taxol used to treat ovarian, breast, and certain lung cancers (Fig. 101.1).

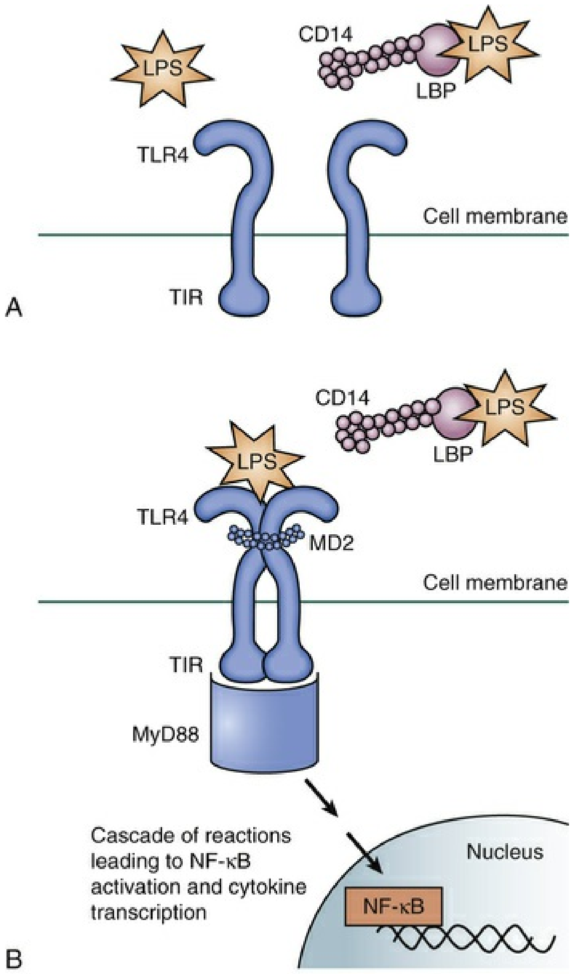

FIG. 101.1 Pathogen-associated molecular proteins and the Toll-like receptor (TLR) pathway. TLR4 is bound to the cell surface (A). TLR forms a dimeric complex along with MD2 to bind lipopolysaccharide (LPS). The LPS-TLR4-MD2 complex causes a conformational change that allows TIRAP to bind to the TIR-domain of TLR4 (B). MyD88 binds to TIRAP, which eventually leads to early NF-κB activation, and transcription of inflammatory cytokines. *LBP*, lipopolysaccharide binding protein; *MyD88*, myeloid differentiation factor 88; *NF-κB*, Nuclear factor κB; *TIR*, Toll/interleukin-1 receptor.

TLR2 recognizes lipoteichoic acid from gram-positive bacteria, lipoarabinomannan from mycobacteria, zymosan from fungi, and hemagglutinin from measles viruses, among others. TLR2 forms complexes with TLR1 and TLR6 to mediate DAMP recognition. TLR5 is present mainly in gut mucosal dendritic cells and recognizes bacterial flagellin. In doing so, it can activate the adaptive immune system to mount a more specific response to pathogenic bacteria in the gut.

The intracellular membrane-bound TLRs[3,7,8,9] are instrumental in defending against invasive pathogens. They recognize nucleic acids, especially pathogen-associated nucleic acids such as double-stranded (ds) RNA and unmethylated CpG DNA motifs not seen in mammalian cells. TLR3 recognizes dsRNA during the replication of single-stranded RNA viruses including RSV. TLR3 deficiency in humans is associated with a susceptibility to infection with herpes simplex virus type 1. TLR7 recognizes RNA viruses, as they are transported in autophagosomes, as well as bacterial RNA from group B *Streptococcus.* TLR8 is also active against

bacteria, and expression can be up-regulated in bacterial infection. TLR9 senses bacterial DNA (unmethylated CpG motifs) but also recognizes hemozoin, which is generated after the digestion of hemoglobin by *Plasmodium falciparum* (Fig. 101.2).

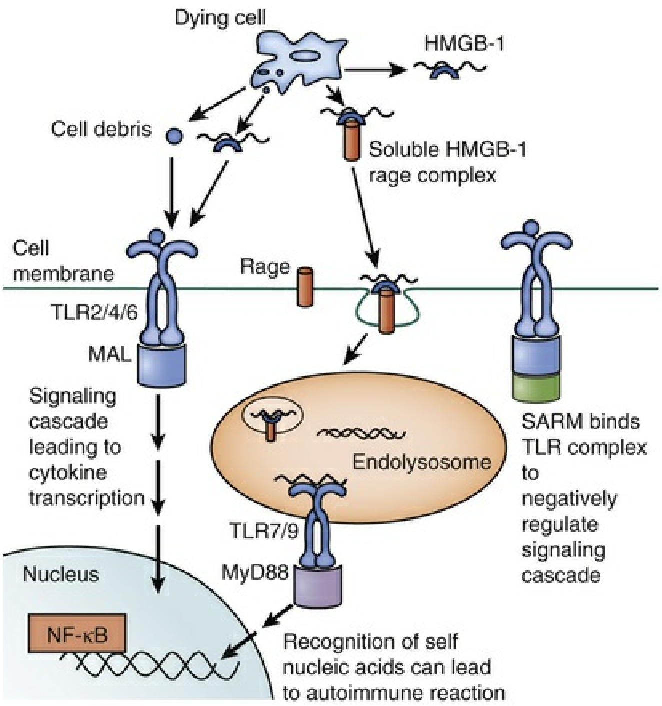

FIG. 101.2 Danger-associated molecular patterns and the Toll-like receptor (TLR) pathway. Cell debris released from a necrotic cell binds to soluble and cell surface receptors (eg, HMGB-1 binds to RAGE). Debris may also directly bind to TLR receptors 2/4 or 6 leading to an inflammatory cascade. Nucleic acids in particular and HMGB-1 are internalized into endolysosomes, where they bind to TLR7 and TLR9. This also leads to an inflammatory cascade, including an autoimmune reaction. The cascade is negative regulated by the TIR domain adaptor protein sterile α and armadillo motif–containing proteins SARM to prevent overwhelming inflammation. *HMGB-1*, high-mobility group box-1; *MAL*, MyD88 adaptor-like protein; *RAGE*, receptor for advance glycation products.

Three major classes of cytoplasmic PRRs are not membrane bound: **n**ucleotide-binding and oligomerization domain-**l**ike **r**eceptors (NLRs), **R**IG-I–**l**ike **r**eceptors (RLR), and **a**bsent **i**n **m**elanoma 2 (AIM)–like receptors. NLRs are the best described cytoplasmic PRRs. Similar to TLRs, they have three distinct domains: Knockout mice deficient in one domain of NLRs (NOD-1 −/− mice) are susceptible to *Staphylococcus aureus* and *Helicobacter pylori* infections; NOD-2–deficient mice are prone to infections from *Toxoplasma gondii*.[10]

Signal Transduction

Once PRRs recognize a signal, they need to trigger a response. In order to do so, they send signals to effector pathways using second messengers.

Circulating PRRs can directly activate the complement system via the lectin pathway. MBLs form complexes with MBL-associated serine proteases (MASPs),

which cleave C4 and C2 to form a C3 convertase. C3 convertase cleaves C3 into active components C3a and C3b. This leads to an antiinflammatory cascade, opsonization of phagocytic cells, and the formation of the complement membrane attach complex. Other soluble-protein PRRs such as defensins can act directly as opsonins and chemotactic particles.

Cell surface and intracellular PRRs have **T**oll/**I**nterleukin-1 **R**eceptor (TIR)-containing domains, which interact with intracellular signaling molecules. Following TLR recognition of DAMPs, the cytosolic TIR-containing domains undergo structural reorganization, which provides a platform for the interaction with a family of adaptor molecules. These include myeloid differentiation primary response 88 (MyD88), the prototypic adaptor molecule involved in the LPS-TLR4 pathway. When bound to activated TLR4, MyD88 recruits a family of kinases, IL-1R–associated kinases (IRAKs), in a complex. Following a cascade of interactions, nuclear factor κB (NF-κB) is activated. The result is the transcription of cytokines leading to an inflammatory response (Figs. 101.1 and 101.2).

As with so many other arms of the innate immune system, there is significant redundancy among adaptor molecules and the signaling pathway. However, MyD88-deficient mice show reduction of NF-κB activation in all TLR pathways apart from TLR3 and TLR4, underlying its importance. The adaptor proteins also have a regulatory function: The adaptor protein **s**terile-alpha and **ar**madillo **m**otif–containing protein (SARM) negatively interacts with the adaptor protein TRIF, limiting the downstream activation of NF-κB.[11]

Effector Pathways

In order for the innate immune system to be effective, it must respond to danger rapidly. The aim of the response is to neutralize the threat where possible, raise the alarm, and seek reinforcements. The effector response can be broadly divided into two arms: *the soluble mediator response,* which has both widespread systemic effects and more targeted local effects, and *the cellular response,* which aims to neutralize directly danger through phagocytosis and self-destruction.

The soluble mediator response: The signal transduction pathways described activate nuclear transcription factors such as NF-κB. Cytokine production is an end point of activation of NF-κB. The inflammatory cytokines include TNFα, IL-1b, IL-4, Il-6, IL-10, IL-12, IL-18, CCL4-RANTES, and transforming growth factor-β. The specific subset of cytokines that is produced and released depends on the innate immune cell type involved. Although NF-κB is the prototypic transcription factor downstream of the innate immune signaling pathways, more recently transcription factor EB (TFEB) has been described as a potentially important mammalian factor in innate immunity. Unlike nuclear NF-κB, TFEB exists in the cytoplasm of macrophages. Upon activation, TFEB moves to the nucleus and leads to transcription of proinflammatory genes. The lack of TFEB in mouse macrophages leads to the inability to produce proinflammatory cytokines in following *S. aureus* infection.[12]

The soluble mediator arm has a widespread systemic effect, as well as a local effect to contain and neutralize the danger signal.

1. Systemic cytokine effects: Systemic effects rapidly follow the exposure to danger. These include the production of fever: TNFα and IL-1B among other cytokines act on the hypothalamus to increase the temperature set point. The fever response is likely

to have a beneficial response in the immune response. In several species, controlling this fever response has a detrimental effect on survival. Observational evidence in humans suggests that the lack of a fever response in critical illness is associated with an increase in mortality.[13] The exact mechanisms of how fever lends itself to immunity are not yet fully elucidated, but it is likely to be multimodal: from decreased pathogenicity of microorganisms to improved immune function. The effects of fever on the immune system include (a) the increased release of neutrophils from the bone marrow, (b) improved localization of neutrophils to tissues, (c) improved phagocytic and cytotoxic activities of neutrophils, macrophages, and natural killer (NK) cells, and (d) increased presentation of antigen presentation to T cells by dendritic cells within lymph nodes.[14]

Cytokines also have effects on the circulatory system and the nervous system through providing nociceptive signals. This mobilizes energy sources to vital organs to fight the danger and may restrict spread between organisms, respectively. Nervous system involvement may also change behavior to avoid noxious stimuli (eg, TNFα knockout mice have a decreased perception of bitter taste, implying that the TNFα sensitizes animals to bitter substances, which may be deemed as noxious).[15]

2. Local neutralization: The complement system, as described earlier, plays an important role in the effector arm of the innate immune system. PRRs activate complement through the lectin pathway. This directly attacks pathogens via the membrane attack complex but also via opsonization and chemokinesis.[16] Cytokines also have an important role in attracting immune cells to the site of danger (eg, CCL4-RANTES attracts macrophages and NK cells to the site of danger to neutralize the threat). This can lead to a positive feed-forward loop: Cytokines released from local tissue such as endothelial cells initially attract immune cells such as macrophages to the site of danger. The immune cells then produce more cytokines to amplify the signal and get further reinforcements.

The cellular response: The cellular response involves two processes—phagocytosis and self-destruction. Both aim to neutralize the threat of danger where possible and also recruit other immune mechanisms such as the adaptive immune system.

1. Phagocytosis: DAMP recognition by cell surface PRRs set into motion cytoskeletal rearrangements. These are achieved by adaptor proteins activating cascades of kinases and guanosine triphosphate-ases (GTP)ases, leading to actin polymerization. This results in a phagosome forming and pinching off the cell surface. Activated macrophages are able to internalize >100% of their surface area within 30 minutes. Once internalized, the phagosome may fuse with lysosomes to form a phagolysosome. Here the DAMPs may be neutralized or processed and relocated to the surface, where they can be presented to T cells to promote an adaptive immune response. Reactive oxygen species (ROS) and nitric oxide are both involved in the neutralization of DAMPS within the phagolysosome. Both are produced during an innate immune response.[17]

2. Self-destruction: Because phagocytosis is the process by which cells internalize and neutralize extracellular material, autophagy is the analogous process for

cytoplasmic protein and organelles: the controlled destruction of cellular material following damage. Autophagy is an essential part of cell maintenance and survival: Multiorgan failure seen in an inflammatory response is postulated as not being sequelae of disease but rather an adaptive mechanism in response to a reduction in available energy.[18] Autophagy is initiated following damage-induced expression of a family of autophagy-related genes (ATGs). The ATG-encoded proteins assemble to form an autophagosome, a double-membrane structure, which envelopes the damaged proteins or organelles. The autophagosome eventually fuses with a lysosome, where the protein or organelle gets enzymatically degraded.[19] Autophagy may result in cell death once all the organelles undergo autophagy and the autophagic cell eventually undergoes phagocytosis. Much as autophagy is an effector of the immune response, as is cell death. This is particularly important following damage, or infection with intracellular pathogens, when the pathogen cannot be controlled. Traditionally cell death has been described as apoptosis (programmed cell death) and necrosis (accidental cell death). However, as the mechanisms behind cell death have been discovered, this distinction has proved to be an oversimplification. Currently five types of cell death are described (Table 101.2).

TABLE 101.2

Modes of Cell Death: Apoptosis, Autophagy-Related Cell Death, Necroptosis, and Pyroptosis Are All Forms of Programmed Cell Death, Whereas Necrosis Is Accidental

Mode of Death	Triggers	Signaling Pathways	Terminal Event	Proinflammatory?
Apoptosis	TNFα, Fas ligand (FasL), TNF-related apoptosis-inducing ligand (TRAIL) Infection	Caspase (3, 6, 7)	Nuclear condensation Nonlytic cell shrinkage Cell blebbing Phagocytosis of apoptotic bodies	No
Autophagy-related cell death	Nutrient deprivation Hypoxia Infection Histone deacetylase inhibitors	Autophagy-related gene activation mTOR Autolysosome formation	Phagocytosis of autophagic bodies	No
Necroptosis	TNFα, FasL, TRAIL Ischemia Infection	TNF receptor signaling Loss of mitochondrial inner membrane potential ROS formation	Organelle swelling Nonlytic loss of cell membrane	Yes
Pyroptosis	DAMPs Infection	NOD-like receptors activation, Caspase-1–dependent inflammasome	Cell swelling Pore formation Cell lysis	Yes
Necrosis	Toxins Infections Inflammation Trauma	(Nonprogrammed)	Cell lysis	Yes

Adapted from Inoue H, Tani K. Multimodal immunogenic cancer cell death as a consequence of anticancer cytotoxic treatments. Cell Death Different. 2014;21:39-49.

Cell death leads to the release of DAMPs following cell lysis, which recruits other parts of the immune system. This is particularly important following trauma and tumor formation.[20]

Crosstalk Between Systems

The innate and adaptive immune systems interact continuously. Considering them as separate systems reflects an enormous simplification. Coagulation, neuroendocrine, cardiovascular, and autonomic nervous systems all influence, and are influenced by, immune responses. At the simplest level this is shown by many molecules having important properties in multiple systems (eg, acetylcholine is a neurotransmitter and a paracrine regulator of lymphocytes, epinephrine has profound cardiovascular effects but also stimulates the bone marrow to release neutrophils into the circulation). High plasma glucose levels arising from the stress response and insulin resistance during critical illness may inhibit complement binding to and killing of microorganisms.

The interaction between the innate immune system and the coagulation cascade is particularly important in critical illness, especially in the context of sepsis and trauma. Plasminogen activator inhibitor 1 (PAI-1) is a potent inhibitor of fibrinolysis. It achieves this response by inhibiting both tissue and urinary type plasminogen activator. Levels of PAI-1 are increased after trauma and sepsis, especially so in severe meningococcal sepsis. Inflammatory mediators TNFα, IL-1 and IL-6, complement 5a, and LPS all act to increase PAI-1 production. In turn, PAI-1 contributes to a procoagulant state and inhibits neutrophil apoptosis. Although this may help to contain inflammation at the site of infection, genotypes associated with high levels of PAI-1 production are associated with worse outcome in septic shock. So there is a direct link between how readily the immune system triggers an increased clotting tendency in critical illness and poor outcome.[21]

Similarly, inflammatory mediators such as IL-6 and HMGB-1 stimulate release of the potent coagulation activator tissue factor (TF) from activated monocytes, macrophages, and endothelial cells. Small membrane vesicles from apoptotic cells known as *microparticles* bind to cell surfaces through specific receptors, expressing TF. This promotes thrombin formation, which in turn converts fibrinogen to fibrin. Thrombin and fibrin generation are increased in inflammation, in part because fibrinolysis is impaired due to increased activity of PAI-1 but also secondary to diminished activated protein C (APC) and tissue factor pathway inhibitor (TFPI). These processes have been the targets for numerous clinical trials of drugs with anticoagulant/profibrinolytic actions—all aiming to achieve antiinflammatory effects by targeting coagulation systems. APC may also have other antiinflammatory actions, down-regulating inflammatory cytokines, preventing the loss of the endothelial barrier, and acting as an antioxidant and antiapoptotic agent. Although initial trials suggested therapeutic benefits of APC in sepsis, this has since been contradicted in larger trials in both children and adults.[22-24]

Another example of a novel interaction between the coagulation and immune systems is that TLR4-activated platelets interact with neutrophils to trap and kill bacteria in so-called "neutrophil extracellular traps" (NETs) (Fig. 101.3). In vitro studies showed that LPS, as well as plasma from septic adults, could induce this phenomenon.[25]

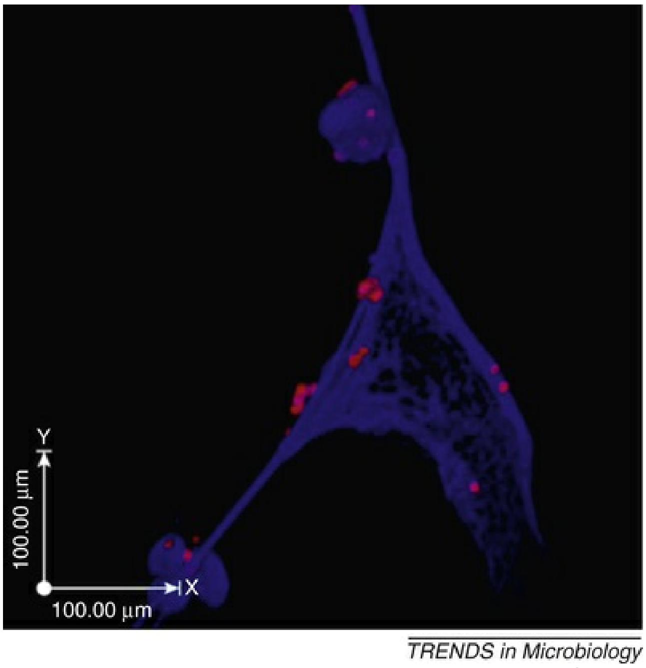

FIG. 101.3 A scanning electron microscope image of a neutrophil extracellular trap. Neutrophils release an extracellular trap made of histones and DNA, along with proteases and antimicrobial peptides. They entrap pathogens, with the DNA exhibiting intrinsic antimicrobial properties. (From Baums CG, von Köckritz-Blickwede M. Novel role of DNA in neutrophil extracellular traps. Trends Microbiol. 2015;23:330-331, Fig. 1.)

Regulation of the Innate Immune Response

As with any physiologic response, the innate immune response needs regulation: to balance the sensitivity of the response against the potential to overreact and cause harm to the host. Key regulatory mechanisms are for the innate immune system are summarized in Table 101.3.

TABLE 101.3

Examples of Regulatory Mechanisms Controlling the Innate Immune Response: Loss of Regulation Can Lead to Diseases Such as Hemophagocytic Lympho-Histiocytosis

Regulation	Example
Negative feedback	Antiinflammatory arachidonic acid–derived lipoxin released after prostaglandin to inhibit granulocyte migration and promote phagocytosis[26]
Cellular compartmentalization	Lipopolysaccharide-stimulated migration of TLR7 and 9 from the endoplasmic reticulum to the endolysosome[9]
Tissue dependence	IL-10 on mucosal surfaces has baseline antiinflammatory effect preventing response to microbiota; released by LPS-stimulated TLR4[27]
Redox state	In apoptosis the mitochondrial outer membrane is permeabilized, arresting the respiratory chain Reactive oxygen species generate oxidize HMGB-1, making it nonimmunostimulatory[28]
Energy state	Mammalian target of rapamycin (mTOR) phosphorylated in states of energy abundance inhibiting autophagy: This is released in energy-depleted states[29]
Hormonal control	Vitamin D–dependent defensin and cathelicidin production (both PRRs)[30] Steroid and catecholamine up/down-regulate cytokine production[31,32]
Microbiome interactions	Gut microbiome activates the NLR3-inflammasome to induce pro IL-1β, but not its cleavage into IL-1β–pathogenic bacteria invading the microbiome and then induce the cleavage of pro IL-1β,

	producing a rapid inflammatory response[33]

Clinical Manifestations of the Innate Immune Response in the Intensive Care Unit

The innate immune system is the body's front-line defense patrol against danger. All patients admitted to the ICU will have activated an innate immune response. In some cases this response may itself be deleterious: either through amplification in the face of an insurmountable threat or through dysregulation of the response. In other cases the critical illness may be a result of an inadequate response.

The prototypic description of the innate immune response is based on the sepsis model.

However, many other pathologic processes in the ICU start with an innate immune response:

1. Hypoxic ischemic injury: Hypoxia, either systemic hypoxia such as at high altitude or localized hypoxia such as in solid tumors, leads to the activation of an innate immune response. Oxygen status is sensed by proline hydroxylases, which act on the proline residues of hypoxia-inducible factors (HIFs) 1a and 2a. This allows the binding of an E3 ubiquitin ligase complex, which inactivates HIFs. Hypoxia releases this inactivation. HIFs set off a cascade of downstream pathways, including the activation of NFκB, the transcriptional regulator that is a key factor in the TLR response to LPS. The overall effect in hypoxia is for the innate immune cells to increase phagocytosis and antimicrobial killing, prevent apoptosis of neutrophils, increase antigen presentation, and increase endothelial adhesion and cytokine release. HIF-deficient myeloid cells are unable to overcome pathogens effectively but form chronic ulcerative lesions. Adaptive immunity pathways are, however, down-regulated to prevent an overactive response.
TLR pathways also play an important part in the ischemic response. TLR4-deficient donor kidneys have better graft function following transplantation compared with kidneys with functional TLR4 receptors.[34]

2. Trauma: Trauma leads to a varying degree of cell necrosis, which is inflammatory. Cell necrosis releases alarmins, such as HMGB-1, into the circulation and activates an innate immune response. In the ICU, this is often seen post surgery, especially so after cardiopulmonary bypass during cardiac surgery.[35] TLR2 and TLR4 both increase their expression on mononuclear cells post cardiac surgery, which typically occurs over a 48-hour period before returning toward baseline. There is a concomitant rise in the proinflammatory cytokine IL-6. The response is stronger if there is cerebral ischemia, as occurs during deep hypothermic circulatory arrest.[36]

3. Acute kidney injury: The renal tubules are exposed to large numbers of signaling molecules and cytokines and are therefore prime candidates for danger recognition. For example, kidney epithelial cells express CD40 receptors on their cell surface: Activation of CD40 leads to an increase in ROS production and prevents apoptosis of the tubular cells. The pathway activates a proinflammatory response, with production and release of inflammatory cytokines. This is a common pathway of

organ crosstalk in the ICU: Injury to one organ may result in a multiorgan effect. An overwhelming or dysregulated immune response locally within one organ, such as the lung in ARDS, can lead to multiorgan failure as large concentrations of inflammatory cytokines are sensed by distant organs.

4. Macrophage activation syndrome (MAS) and hemophagocytic lymphangohistiocytosis (HLH): These diseases represent a broad spectrum, ranging from familial varieties with recognized to genetic mutations, to those associated with rheumatologic inflammatory conditions. This is an example of a dysregulated immune response. Ineffective cytotoxic activity of NK cells means an inability to effectively neutralize a threat such as a viral infection. This is a deficiency of the major "immune off-switch" of induced apoptosis of virally infected cells and results in a persistence of immune activation. The result is proliferation of phagocytes and a flood of proinflammatory cytokines, leading to a destructive systemic inflammatory state.

Therapeutic Targets of the Innate Immune System

Given the ubiquity of innate immune system activity, often to the detriment of the intensive care patient, it should offer several effective therapeutic targets. Sadly, although many "magic bullet" solutions have been sought, such as activated protein C and bactericidal/permeability-inducing protein (BPI), none have been found to be effective. The reasons for this are complex, but two possible reasons are immediately apparent: (1) evolution has furnished the innate immune system with a high degree of redundancy, in order to be "fail-safe." Therefore targeting one component of the signal or response may be mitigated by a separate arm of the pathway. (2) The immune response is a juxtaposition of two opposing forces: a proinflammatory response to a threat, followed by a regulatory antiinflammatory restitution to baseline. Both are necessary, but both can become maladaptive. Any therapeutic measures therefore need to target the maladaptive process specifically. Attaining this level of specificity against either the proinflammatory or antiinflammatory arm, without disrupting the other, is difficult. Instead, the treatment may have to be adjusted according to the inflammatory profile at the time. Attention has now been diverted to accurate profiling of the inflammatory response, using genomic, transcriptomic, proteomic, and metabolomic biomarkers.

Therapeutic Questions Arising From the Innate Immune System

The innate immune system is relevant to many interventions in the ICU. Many molecules central in (superficially) nonimmune physiologic processes play a role in the immune response.

1. Can oxygen be harmful?
Matching oxygen delivery to consumption is the foremost physiologic aim in the

ICU. Measuring oxygen consumption with any degree of accuracy is difficult clinically. Oxygen delivery is estimated and guided by surrogate markers such as lactate and central venous saturations. Hypoxia is harmful and can initiate an immune response through HIF activation. In an attempt to avoid hypoxia, there is a tendency to err toward hyperoxia. However, it is emerging that hyperoxia can similarly cause harm. Although ROS is important in the innate immune response as described earlier, it is also toxic, as demonstrated by the utility of ROS in phagolysosomes. Hyperoxia increases ROS production, tipping the balance toward damage. In the mouse lung model, hyperoxia leads to ROS-mediated DNA damage, inflammation, and loss of barrier integrity. Unexpectedly, the proinflammatory effects of the TLR4-mediated pathways are not responsible for the damage (and subsequent death of mice), but rather the TLR4-dependent pathways are protective, by triggering antioxidant and proapototic pathways. Hyperoxia also affects pulmonary macrophage function, impairing their ability to kill pathogens.[37] This effect, likely mediated by HMGB-1 pathways, is important given the risk of ventilator-associated pneumonia in the ICU. Hyperoxia also seems to have longer-term effects; experienced in the neonatal period, it can alter the ability to fight influenza A in adult mice, thought to be mediated by both changes in epithelial cell PRRs and programming of hematopoietic cells.[38]

Clinically, hyperoxia has been associated with poor outcomes. This is most often shown in the context of cardiac arrest: hyperoxia following a period of ischemia, leading to an ischemia-reperfusion injury.[39] Therefore careful attention needs to be paid to oxygen use in the ICU. Randomized controlled trials are needed to identify the optimal oxygen level in different phenotypes (eg, as in preterm neonates).[40]

2. Is nutrition always beneficial?

Critical illness is a catabolic state with an increase in energy utilization. This has traditionally been believed to be due to the increase in metabolic activity to mount an immune and inflammatory response. This may be an oversimplification. Recent thinking suggests that there is an active switch from aerobic glucose metabolism to anaerobic glycolysis. This is known as the *Warburg effect,* first described in cancer cells. The driver for such a switch in cancer cells is initial hypoxia, activating HIFs, which inhibit pyruvate dehydrogenase. The effect of such a metabolic switch is to prevent apoptosis (due to loss of mitochondrial membrane potential and dysfunction) and increase cell proliferation. In sepsis the Warburg effect is seen in monocytes and macrophages in order to proliferate and mount an effective response. The use of glycolysis for energy production requires a large amount of glucose; therefore glucose uptake and protein and lipid breakdown are up-regulated. Traditionally intensive care physicians have attempted to provide nutrition to match this energy-hungry catabolic state. Studies of early supplementation of enteral nutrition with parenteral nutrition to meet estimated nutritional needs have suggested that those without supplementation may be discharged alive from ICU earlier, although the overall mortality in both groups was the same.[41] However, those with no supplementation had fewer infections in the ICU, as also seen in trials comparing early versus late initiation of parenteral nutrition. This is proposed to be related to protein intake, particularly parenteral nutrition rather than enteral nutrition. The mechanism for this effect is not known: It is hypothesized that the increase in nutrition leads to impaired autophagy and therefore inefficient cellular

metabolism and DAMP production.[42]
The route of nutrition can have an important effect on the immune response. Neutrophils exposed to parenteral lipids show impaired ability to eliminate pneumococci.[43] In contrast, enteral nutrition may have a beneficial effect on the innate immune response, through the effect of enteral nutrition on intestinal integrity and the gut microbiome. The microbiome has a protective effect on gut integrity as described earlier. However, specific nutritive interventions have not necessarily had the magnitude of effect expected: Probiotics have been shown to be effective in the treatment of *Clostridium difficile* infections but have not had a significant effect in overall critical illness outcomes.[44] In neonates, the gut microbiome is least poorly established. Meta-analysis evidence points to a survival benefit with probiotic treatment in preterm necrotizing enterocolitis.[45]
Compared with the nutritional addition of probiotics, manipulation of the microbiome using selective digestive tract decontamination (SDD) shows reasonable promise: Good-quality evidence points toward the effects of SDD in reducing hospital-acquired infections in the ICU.[46]
Finally, the concept of immunonutrition has emerged to provide specific supplements in nutrition, either enterally or parenterally, to modulate the immune response. Glutamine is used by several cells involved in the innate immune response: neutrophils, macrophages, and enterocytes. It is easily depleted in critical illness and has manifold functions. Although initial studies pointed to a potential benefit in critical illness outcomes, especially in some cohorts such as burns patients, larger trials have not borne this out. Arginine, necessary for nitric oxide production, may help reduce hospital-acquired infections but has not shown a mortality benefit in critical illness. Antioxidants such as selenium, zinc, copper, and vitamins B, C, and E have shown promise in reducing mortality in some patient groups (trauma, cardiac patients) and may also reduce hospital-acquired infections. Currently, the evidence does not support use in all patients in the ICU, and the evidence in children is lacking.

3. Should catecholamine use be limited?
Catecholamines, as described, have effects on the immune system while also promoting pathogen proliferation and virulence. Catecholamines are necessary in the intensive care armory, now more so given the recent doubts cast over the association between fluid resuscitation and mortality in sepsis. The risks and benefits of using catecholamines have not been directly demonstrated, but there is enough supportive evidence for their use. However, whether catecholamine use needs to be better tailored to the individual immune profile is yet to be determined. Catecholamines have wide-ranging effects: hemodynamic, metabolic, and endocrine in addition to the immune effects. Teasing out the beneficial and detrimental effects of each property will be challenging. For now, catecholamine use must be supported, but use should be titrated to effect closely, being mindful of the immunosuppressive and pathogen-promoting effects of catecholamines.[32]

4. Should fever be treated?
Despite the conservation of fever as an immune response across a wide range of species evolution, we are yet to be convinced that it has a beneficial role in overcoming danger. Preventing fever in most animal classes seems to increase

mortality. In humans, fever reduces time to recovery in varicella infections, reduces rhinovirus shedding, and increases malaria parasite clearance. Concern exists in critically ill patients regarding the energy expenditure needed to produce a fever and the hemodynamic effects, such as tachycardia and hemodynamic changes. Two recent observational studies in the intensive care environment have challenged this concern. A retrospective review of more than 600,000 patients admitted to the ICU demonstrated that a peak temperature above 39°C in patients admitted with infective illness has a reduced risk of mortality.[14] This points toward a beneficial effect of fever in critical illness, particularly in those with infection. This is likely to be mediated by neutrophils: The neutropenic subpopulation in the first study did not show the beneficial effect of fever. Fever increases both ROS and nitric oxide species production by neutrophils: This may be a potential mechanistic explanation.[47] Alternatively, the interventions to reduce temperature may be detrimental. To further explore this, a large multicenter trial compared paracetamol versus placebo treatment of fever. No differences were seen between the two groups, although the temperature profiles for both groups were similar both before and after treatment.[48]

5. Does sedation just reduce metabolic demand?

So far we have not mentioned the role sedation may play on the immune system, despite the widespread use of sedation in the ICU. However, while sedation may be thought of as beneficial, in order to reduce metabolic demand in critical illness, the innate immune system does not escape its effects. Epidemiologically, chronic IV opiate abusers have been observed to present with a high number of infections. Macrophages and neutrophils have been known to have μ-opioid receptors. Morphine reduces macrophage recruitment, phagocytosis, and the respiratory burst in vivo. In mice, this leads to reduced bacterial clearance, an effect that was abolished in μ-opioid receptor knockout mice and by naltrexone. In addition, there is a suppression of chemokine production following morphine exposure, through suppression of NF-κB. Similarly, neutrophil recruitment is also suppressed by opioids, although there may be a differential effect of exogenous (suppressing chemotaxis) and endogenous (promoting chemotaxis) opioids. Acute morphine treatment has been shown to delay wound healing in laboratory models. However, currently there is no trial evidence in humans to suggest opioids delay recovery in intensive care patients.

Benzodiazepines are commonly used as sedative agents in the pediatric ICU. Peripheral (non-GABA) binding sites for benzodiazepines are present on immune cells including macrophages and neutrophils. Neutrophil chemotaxis can be inhibited in vitro by benzodiazepines. NF-κB activation is reduced by midazolam in macrophages, with a suppression of proinflammatory cytokines such as TNFα. Furthermore, lipopolysaccharide-induced superoxide production is inhibited by benzodiazepines in neutrophils and macrophages in vitro, affecting successful cytotoxic activity. Induced nitric oxide and cyclo-oxygenase activity is also reduced by benzodiazepines. In animal models of pneumonia, benzodiazepine treatment increases mortality.

Sedative centrally acting α_2-agonists, clonidine and dexmedatomidine, do not affect human neutrophil chemotaxis, phagocytosis, or superoxide production in vitro. In animal models of sepsis, pretreatment (ie, before the induction of sepsis) with

clonidine reduces NF-κB activation and cytokine production (as benzodiazepines) but reduces mortality by dampening the systemic inflammatory response.[49,50] Why do benzodiazepines and α_2-agonists have different effects on animal models of infection even though cytokine production is reduced by both? The differences may be more subtle than cytokine production—both agents have receptors on a variety of cell types and therefore have widespread actions. However, the effects of sedatives, as with any modulators of the immune response, may depend on the exact immune profile at any given time (eg, the balance of proinflammatory and antiinflammatory cytokines that lead to the immune phenotype). In the subgroup analysis of a trial comparing lorazepam-based sedation against dexmedetomidine, those sedated with dexmedetomidine were less likely to die or have brain dysfunction. This effect was more pronounced in the context of sepsis. Although this adds to the speculation that α_2-agonists may have immune-favorable effects in critical illness, further mechanistic work with better phenotypic categorization is needed to prove this.

Conclusion

The innate immune system is the first line of defense against danger, both endogenous and exogenous. The pathways are complex, involving a large number of redundant processes and several orders of interactions between pathways and systems. Many molecules and cells involved in the innate immune system also have nonimmune functions. The innate immune system therefore should be thought of as not only a dedicated police force but also a neighborhood watchscheme. This has particular relevance in the ICU, as many of our interventions can affect the innate immune function. So while we are yet to harness our knowledge of the innate immune system to develop new therapies, there is probably more scope to better use existing therapies so as to not jeopardize the protective benefits of the innate immune response.

CHAPTER 102

Adaptive Immunity

W. Joshua Frazier, Kristin C. Greathouse, Jennifer A. Muszynski

PEARLS

- Unlike the innate immune response, the adaptive immune response is characterized by specific antigen recognition and immunologic memory.
- Lymphocytes are the key cell types of the adaptive immune response.
- B lymphocytes differentiate into antibody-secreting plasma cells and are responsible for humoral immunity.
- $CD8^+$ T lymphocytes differentiate into cytotoxic T cells, which function to control viruses and other intracellular pathogens by directly killing infected cells.
- $CD4^+$ T lymphocytes differentiate into a myriad of helper T-cell subsets, which regulate and coordinate the overall immune response and span a spectrum from highly proinflammatory to potently immunosuppressive function.

Introduction

The adaptive immune system is generally considered an additional line of defense after innate immunity. There are several important differences between the innate and adaptive immune systems. First, adaptive immunity takes more time to develop than the rapid onset of inflammation induced by innate immune cells. Second, rather than the more nonspecific activation of innate immune cells by pattern recognition receptors, components of the adaptive immune system develop to recognize specific pathogens. Finally, immunologic memory is a hallmark of the adaptive immune system, which allows for a more rapid and robust immune response upon repeated exposure of the same pathogen. Although it is helpful to consider the innate and adaptive immune systems as distinct, in reality these two systems rely heavily on each other for activation and coordination of an overall immune response. Consequently, there is a great degree of crosstalk between the two systems, which will be highlighted throughout this chapter.

The primary cell types of the adaptive immune response are lymphocytes, which can be broadly classified into B cells and T cells. B cells differentiate into plasma cells and function primarily to produce antibodies, essential for humoral immunity. T cells, by contrast, differentiate into effector cells with a variety of functions, including killing infected cells, directing the activation or suppression of innate

immune cells, promoting innate immune cell migration, and enhancing barrier and immunologic function of epithelial cells. This chapter focuses on the cellular components of adaptive immunity. The chapter begins with a brief overview of B-cell and T-cell development, followed by a discussion of B-cell function and humoral immunity. Next, the authors discuss T-cell activation followed by differentiation and function of first $CD8^+$ cytotoxic T cells then $CD4^+$ T helper cells. The chapter concludes with an introduction to adaptive immunity in the ICU.

Lymphocytes Develop to Recognize Specific Antigens

B cells and T cells are so named for their respective sites of maturation: bone marrow for B cells and thymus for T cells. The development of both cell types has many similarities, which result in a diverse repertoire of lymphocytes, each able to recognize a specific antigen. Both B and T lymphocytes arise from common lymphoid progenitors, which derive from hematopoietic stem cells. B cells develop in response to transcription factors EBF, E2a, and Pax-5, whereas the transcription factors NOTCH-1 and GATA-3 drive T-cell development. For both cell types, one of the earliest steps in development involves gene rearrangements in the antigen recognition regions of the immunoglobulin heavy chain locus (B cells) or the T-cell receptor (T cells). This gene rearrangement process is necessary to develop a wide array of cells with specific antigen recognition regions. The next steps involve positive and negative selection, resulting in a final repertoire of cells capable of recognizing processed foreign antigen while not reacting to self-antigens. Immature B cells express IgM on their surface. If they bind strongly to self-peptides in the bone marrow, they are either depleted or they undergo further gene rearrangements in a process called receptor editing. B cells that survive negative selection leave the bone marrow and migrate to peripheral lymphoid organs where they await activation and further maturation to antibody-secreting plasma cells.

Immature T cells undergo both positive and negative selection in the thymus. Positive selection is carried out in the cortex of the thymus where T cells that recognize peptides presented by dendritic cell major histocompatibility complex (MHC) molecules survive. Negative selection occurs after positive selection and is carried out in the corticomedullary junction of the thymus. Here, T cells that have either strong affinity or no affinity to self-peptides bound to MHC molecules are deleted by apoptotic cell death. Meanwhile, immature T cells with weak affinity for self-peptides bound to MHC survive. In this way, surviving T cells are capable of recognizing self-MHC molecules but do not react strongly to self-antigens. These surviving T cells (naïve T cells) leave the thymus and continuously circulate through and among peripheral lymphoid organs, making multiple contacts with resident antigen-presenting cells capable of T-cell activation.

B-Cell Activation Leads to Antibody Secretion: The Humoral Immune Response

The humoral immune response is driven by antibodies, which are produced

following the stimulation, proliferation, and differentiation of naïve B cells. Naïve B cells are activated in secondary lymphoid organs, such as local lymph nodes or the spleen where they encounter processed microbial protein fragments (antigens) bound to MHC class II proteins on the surface of professional antigen-presenting cells (APCs). Antigen recognition and subsequent B-cell activation often occurs in the presence of specialized helper T cells, which facilitate and direct B-cell differentiation. Once activated by the overlapping signals provided by APCs and helper T cells, B cells proliferate and differentiate. Some B-cell clones develop into plasma cells, which are factories for high-level antibody production. Other clones differentiate into memory B cells, which are long lived and allow for the anamnestic nature of the secondary immune response, whereby subsequent encounters with a pathogen lead to a faster, higher magnitude antibody response. Although a B cell and its antibody products are specific to only a single antigen or epitope, it is important to note that any given microorganism contains many foreign proteins that are potentially antigenic. Indeed, an invading bacterium may contain dozens or hundreds of antigenic peptide sequences, each capable of stimulating a B cell (and likely a T cell). Thus, the majority of humoral immune responses are polyclonal, meaning multiple B-cell populations are engaged in the response and high titers of a wide variety of antibodies are produced, all of which are specific to the pathogen.

Antibodies, also called immunoglobulins (Ig), are the primary product of B cells and constitute the effector element of the humoral immune response. Fig. 102.1 depicts general immunoglobulin structure. The classic antibody is constructed of two heavy chains, bound to each other, and two light chains, each bound to a heavy chain. The variable regions of the heavy and light chains contribute to the formation of the antigen-binding site, also referred to as the antigen-binding fraction (Fab) segment. As their name suggests, variable regions differ among individual antibodies and are responsible for the specificity of the antibody response. The remaining antibody fraction is denoted the Fc portion (for crystallizable fraction).

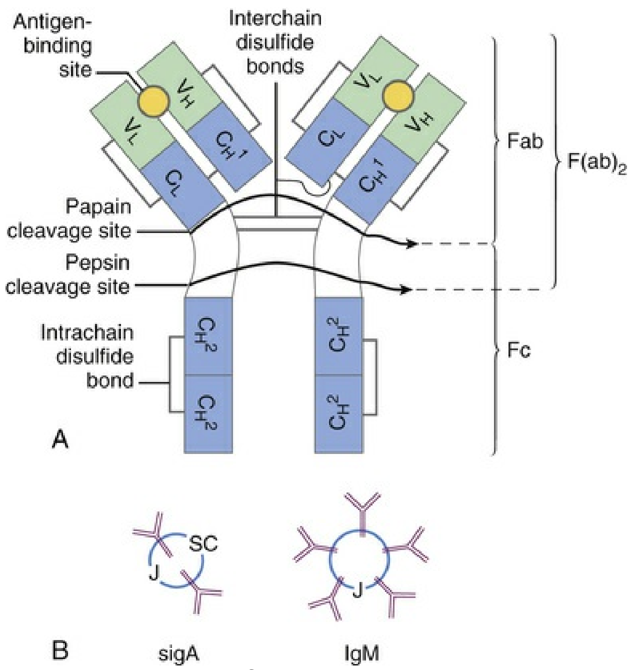

FIG. 102.1 Basic structure of the immunoglobulin molecule. (A) The

stereotypical antibody has a general “Y” shape and is composed of two heavy chains and two light chains bound to each other by disulfide bonds. Both chains contain constant regions, constant heavy (CH) and constant light (CL), of conserved amino acid sequences, which are alike in all antibody molecules of the same class, and variable regions (VH and VL), which are highly variable and unique to the antigen-binding site of each individual antibody. Sites of papain or pepsin proteolytic cleavage result in the Fab and Fc immunoglobulin fragments. (B) IgA and IgM are polymeric antibodies composed of 2 (IgA) or 5 (IgM) basic immunoglobulin chain units.

Antibodies confer protection by two mechanisms: neutralization and opsonization (Fig. 102.2). Neutralizing antibodies slow or halt infection by binding proteins, which confer virulence to the invading microorganism, such as a viral receptor, and preventing them from functioning. Neutralizing antibodies also bind and protect the host from secreted microbial toxins. This ability underlies lifesaving passive immune therapies for infections such as botulism and diphtheria. Opsonization is the process by which Fc receptors on the surface of innate immune effector cells bind the Fc portion of antigen-bound antibodies, facilitating phagocytosis and the killing of antibody-coated microorganisms. In addition to direct opsonization, the exposed Fc portion of bound antibodies also activates the complement cascade. Complement activation further augments the antiinfective response by either directly killing bacteria through assembly of the membrane attack complex or by further opsonization via complement proteins such as C3.

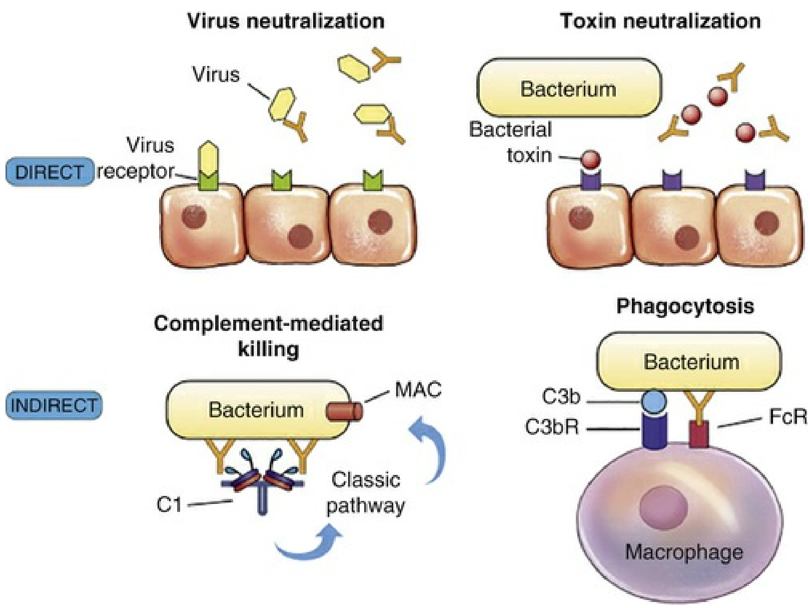

FIG. 102.2 Direct and indirect antibody functions. Antibodies function to directly neutralize microbial virulence factors, such as virus receptors or bacterial toxins. Indirect antibody function includes complement activation and opsonization, whereby phagocytic cells recognize the Fc portion of pathogen-bound antibodies, prompting phagocytosis and microbial killing.

B cells produce antigen-specific antibodies with variations in structure that impact

function. These different antibody classes, or isotypes, add important nuance to the adaptive immune response to infection. Changing the antibody produced by a B cell from one class to another is known as isotype switching or class switching and is mediated by a complex interplay of cytokines and helper T-cell interaction. Specific functions and characteristics of antibody classes are outlined in Table 102.1. Of particular relevance is the temporal relationship between IgM and IgG in the context of new infection. In the primary immune response, in which the adaptive immune system recognizes a previously unencountered threat, the first class of antibody produced after B-cell activation is IgM. Over the course of the immune response, levels of IgM fall and are replaced by high levels of IgG. Subsequent exposure to the same pathogen generates high levels of IgG with a much shorter latency between antigen exposure and antibody production. This temporal relationship comes into play diagnostically when one obtains serologies, or infection-specific immunoglobulin levels, to diagnose infection.

TABLE 102.1

Characteristics of Antibody Isotypes

Isotype (Class)	Functions	Subclasses	Present in Secretions	Placental Transfer
IgG	• Opsonize antigens for phagocytosis • Complement activation • Antibody-dependent cell killing by NK cells • Neonatal immunity via placental transfer	IgG_1	+	+++
		IgG_2	+	+
		IgG_3	+	+++
		IgG_4	−	++
IgM	• Complement activation • Antigen recognition by naïve B cells		+	−
IgA	• Mucosal immunity	IgA_1	+	−
		IgA_2	+	−
		sIgA	++++	−
IgE	• Mast cell degranulation		+	−
IgD	• Antigen recognition by naïve B cells		−	−

NK, natural killer cell.

Aside from their critical role in the adaptive immune response to infectious disease, antibodies have important roles in other aspects of human biology. Antibodies directed inappropriately against self-derived antigens (so-called autoantigens) are key elements in the pathophysiology of autoimmune disease. A classic example is myasthenia gravis, in which autoantibodies bind to the neuromuscular junction, preventing stimulation of muscle fibers and resulting in weakness. Autoantibody-mediated autoimmune diseases are often treated with a combination of immunosuppressive medications and therapies, which reduce antibody titer, such as therapeutic apheresis. Additionally, immunosuppressive therapies to prevent rejection of transplanted organs often involve maneuvers to reduce antibody production—for example, the B-cell reducing agent rituximab.

Due to their ability to recognize and bind specific proteins, antibodies are increasingly used to develop targeted therapies, diagnostic assays, and a multitude of research tools. Indeed, the development of technologies to generate and mass-produce monoclonal antibodies has created many new therapeutic agents and diagnostic tools. An example of monoclonal antibody use that has become ubiquitous in the modern practice of diagnostic medicine is the enzyme-linked immunosorbent assay (ELISA). This powerful tool involves the use of monoclonal antibodies that are specific to certain proteins of interest, such as anti-HIV antibody.

When exposed to a patient sample, the monoclonal antibodies will bind relevant material, if present, from patient blood or plasma. When secondary fluorescent antibody is applied, it is possible to detect and quantify the protein of interest. ELISA is just one of many examples of antibody-based techniques used in both clinical diagnostics and basic/translational research, including Western blot, flow cytometry, immunofluorescence assays, and others.

Effector T Cells Direct Cell-Mediated Immunity

Like B cells, naïve T cells are activated in secondary lymphoid organs, where they proliferate and differentiate into either memory cells or effector T cells. Effector T cells migrate from lymphoid organs to sites of inflammation where they carry out a multitude of functions depending on effector cell type.

T-Cell Activation Requires Interaction With Innate Immune Cells

As was the case with humoral immunity, proper interplay between the innate and adaptive immune systems is vital for activation of cell-mediated immunity. T cells are generally unable to respond to so-called free antigen but require contact with antigenic peptides that have been processed and displayed via MHC molecules on the cell surface. MHC class I molecules are expressed on all nucleated cells in the body and are recognized by $CD8^+$ T cells. Effector $CD8^+$ T cells (also known as cytotoxic T lymphocytes) are designed to kill tumor cells and cells infected with intracellular microbes or viruses. By contrast, $CD4^+$ T cells only respond to peptide presented by MCH class II molecules. MCH class II molecules are found on specialized antigen-presenting cells (APCs). APCs are designed to capture antigen at the site of infection/injury, process it into small peptides, and transport it via the lymphatics for presentation to T cells in secondary lymphoid organs. There are two types of APCs: (1) professional APCs are innate immune cells that constitutively express MHC class II molecules and include dendritic cells, macrophages, and certain B lymphocytes; (2) nonprofessional APCs express MHC class II molecules only when stimulated by certain cytokines such as interferon gamma (IFNγ) and include endothelial and some epithelial cells. Because nonprofessional APCs are not efficient at processing antigen into MHC binding peptides, they likely contribute to a minority of T-cell responses. Dendritic cells, on the other hand, are highly effective professional APCs responsible for the majority of naïve T-cell activation.

Under normal circumstances, each T-cell receptor recognizes and binds to only a specific antigenic peptide bound to the peptide-binding groove of an MHC molecule. This form of activation results in a highly regulated, specific response. Super antigens are an exception to this rule. Super antigens are capable of cross-linking MHC molecules with families of T-cell receptors, thus inducing the activation of large numbers of T cells at once. This cross-linking does not require antigen processing and presentation by innate immune cells and consequently super antigen-mediated diseases can present with a rapidly fulminating course. Such is the case for toxic shock syndrome, which is caused by staphylococcal or streptococcal bacterial toxins functioning as super antigens. Because the signs and symptoms—

and much of the morbidity—of toxic shock syndrome are toxin mediated, antibiotic regimens generally include the addition of clindamycin to decrease toxin production. The addition of intravenous immunoglobulin (IVIG) to deliver toxin-neutralizing antibodies may also be of benefit, with observational studies demonstrating associations between IVIG use and decreased mortality in patients with toxic shock syndrome and other severe invasive group A streptococcal infections.[1,2]

T-Cell Activation Requires a Second Signal

As an additional layer of regulation, T-cell activation requires APCs to deliver two signals (Fig. 102.3). The first is the antigen-specific T-cell receptor (TCR)/MHC interaction. The second signal is the antigen nonspecific costimulatory signal and is provided by the interaction between costimulatory molecules expressed on APCs and receptors expressed by the T cell. If a T cell receives only antigen-specific TCR stimulation in the absence of costimulation, it will be rendered unresponsive to subsequent antigenic challenge. This process, which creates anergic T cells, is an important peripheral mechanism to promote T-cell tolerance to self-antigens. Costimulatory pathways can provide either *positive* signals that promote T-cell proliferation and differentiation or *negative* signals that inhibit T-cell responses and further mediate T-cell tolerance. As such, these pathways provide critical immunoregulatory function.

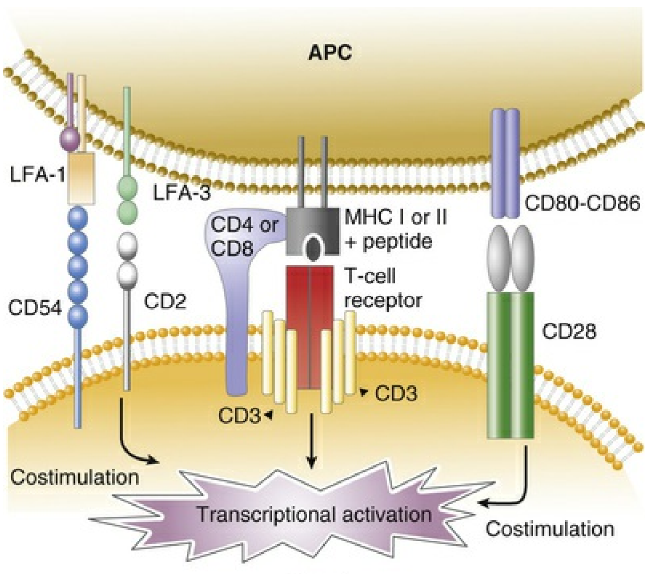

FIG. 102.3 T-cell activation requires multiple signals. T cells and antigen-presenting cells (APCs) interact at the immunologic synapse. Circulating T cells transiently bind APCs allowing the T-cell receptor (TCR) to interact with multiple MHC molecules. Recognition of an MHC-bound antigenic peptide activates integrins, such as lymphocyte function–associated antigen-1 (LFA-1), and adhesion molecules such as CD54, also known as intercellular adhesion molecule (ICAM)-1, which serves to stabilize the immunologic synapse. MHC molecule/antigen recognition by the T-cell receptor/CD3 complex and coreceptor (CD4 or CD8) and a costimulatory signal often resulting from binding of CD28 and B7 (CD80 or 86) family

members are required for T-cell activation.

Table 102.2 outlines costimulatory molecules of the CD28:B7 families. The classic T-cell costimulatory ligand is CD28, which binds B7-1 (CD80) or B7-2 (CD86) molecules expressed on activated APCs. B7:CD28 binding augments T-cell activation by increasing the expression of antiapoptotic proteins, augmenting metabolic activity, enhancing T-cell proliferation, and inducing secretion of the cytokine interleukin-2 (IL-2). Under normal circumstances, the B7 costimulators are either absent or expressed at low levels on resting APCs. Their surface expression is induced by APC activation via toll-like receptor signaling or inflammatory cytokines such as IFNγ. In this way, T-cell activation occurs only in the presence of innate immune cell activation or local inflammation. In turn, activated $CD4^+$ T cells further enhance the expression of B7 costimulators on APCs, which serves as a positive feedback loop for continued amplification of T-cell responses. An important mechanism for this feedback loop is via CD40 on APCs binding to CD40 ligand on activated $CD4^+$ T cells. CD40:CD40L binding further activates APCs, enhancing their expression of B7 molecules and their secretion of cytokines (such as IL-12) to promote T-cell differentiation.

TABLE 102.2

T-Cell Costimulatory Receptors of the CD28 Family and Their Ligands

Receptor	Ligand(s)	Cells That Express Ligand(s)	Effects
Positive Costimulation			
CD28	B7-1(CD80) B7-2 (CD86)	DC, macrophages, B cells	Costimulate naïve T-cell activation
ICOS	ICOS-L	DC, macrophages, B cells	Promote differentiation of follicular helper T cells
Negative Costimulation			
CTLA-4	B7-1(CD80) B7-2 (CD86)	DC, macrophages, B cells	Negatively regulate T-cell response
PD-1	PD-L1(CD274) PD-L2 (CD273)	DC, macrophages, B cells, epithelial cells	Negatively regulate T-cell response

DC, dendritic cell; *ICOS*, inducible costimulatory molecule.

Although the CD28:B7 costimulatory pathway provides positive second signals that promote T-cell activation, cytotoxic T-lymphocyte antigen 4 (CTLA-4) and programmed death 1 (PD-1) are examples of negative costimulatory pathways. CTLA-4, expressed on the surface of T cells, is a high-affinity receptor for B7 molecules. As such, CTLA-4 is capable of binding low levels of B7 on resting APCS displaying self-antigen. CTLA-4:B7 binding then inhibits access of CD28 to B7, which blocks the positive costimulatory pathway.

PD-1 expression on peripheral lymphocytes and monocytes is induced upon activation. Binding of PD-1 to its ligand(s) negatively regulates T-cell responses by inhibiting T-cell receptor signaling and by promoting the differentiation and function of immunosuppressive regulatory T cells. Clinically, the PD-1 pathway is implicated in T-cell exhaustion due to chronic viral illness and may play a role in sepsis-induced immune suppression.[3-6]

$CD8^+$ T Cells Differentiate Into Cytotoxic T Cells

$CD8^+$ T cells are integral to the immune response against viruses and other intracellular pathogens. As discussed earlier, $CD8^+$ T-cell activation begins with

recognition of antigenic peptide presented by MHC I molecules on the surface of an infected cell or an antigen-presenting cell. In some cases, $CD4^+$ helper T cells may help promote $CD8^+$ T-cell development via APC activation or by cytokine secretion. Cytokines that stimulate $CD8^+$ T-cell growth and differentiation include IL-2, IL-12, IFNγ, IL-15, and IL-21. Once activated, $CD8^+$ T cells undergo clonal expansion and differentiation into fully functional cytotoxic T lymphocytes (CTLs). Activated CTLs use one of two mechanisms to kill infected target cells (Fig. 102.4). In the first mechanism, the CTL delivers the cytotoxic protein content of its cytoplasmic granules (perforins and granzymes) to the target cell. Perforins facilitate the transport of granzymes to the cytosol of the target cell where the granzymes cleave caspase proteins, initiating apoptotic cell death. A second method of CTL-mediated target cell death involves the binding of FasL (CD178) on the CTL surface with Fas (CD95) on the target cell surface. Fas:FasL binding initiates a signal transduction cascade leading to caspase activation and apoptosis. In addition to directing target cell death, cytotoxic T lymphocytes secrete the cytokine IFNγ, which serves to activate local macrophages and promote particular helper T-cell responses (eg, T_H1), thus providing additional crosstalk between innate and adaptive immunity.

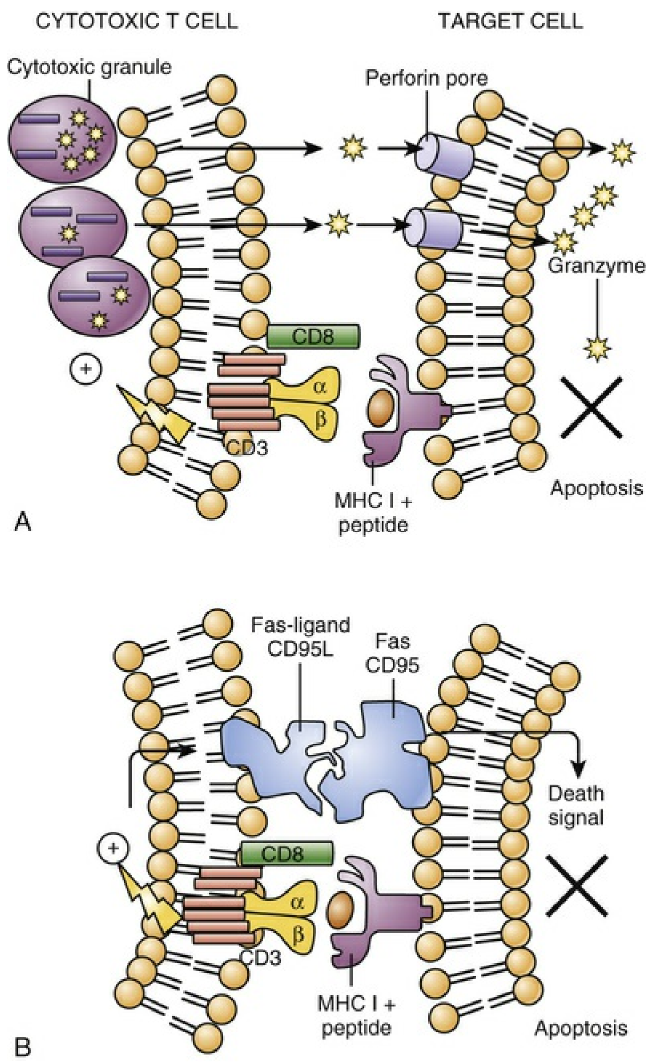

FIG. 102.4 Cytotoxic T cells induce target cell apoptosis by two

mechanisms. (A) Contents of cytotoxic granules (granzymes) are delivered to the target cell via perforin proteins. Granzymes directly activate caspases, initiating apoptotic cell death. (B) Fas-ligand binding to Fas on target cells initiates a signal transduction cascade leading to apoptosis.

CD4⁺ T Cells Differentiate Into Multiple T Helper Cell Subtypes

When naïve CD4⁺ T cells are activated, they proliferate and differentiate into a variety of effector helper T-cell subtypes, each with distinct function and cytokine signatures. Cytokines present in the local environment at the time of T-cell activation largely determine the direction of subtype differentiation. Properties of individual T helper cell subtypes are outlined in Table 102.3. Though it is helpful to think about effector T helper cell subtypes as distinct, fully differentiated cells, evidence suggests that effector T cells retain the ability to change subtype.[7,8] This degree of plasticity coupled with ever increasing recognition of novel T helper cell subtypes speaks to a high degree of complexity, our understanding of which continues to evolve.

TABLE 102.3

CD4⁺ Effector T-Cell Subsets

Subset	Cytokines Directing Development	Cytokines Secreted by Subset	Role in Promoting Inflammation	Functions
T_H17	IL-1, IL-6, IL-23, TGFβ	IL-17, IL-21, IL-22	+ + +	• Recruit neutrophils and macrophages to site of inflammation • Promote G-CSF production to ↑ neutrophil numbers • Promote epithelial cell barrier function • Induce epithelial cell cytokine production
T_H1	IL-12, IFNγ	IFNγ, IL-2, GM-CSF, TNFβ, CCL2	+ +	• Classic macrophage activation • ↑ Macrophage NO, ROS production • Direct B cells to ↑ IgG and ↓ IgE • ↑ T_H1 differentiation and ↓ T_H2
T_{FH}	IL-6, IL-21	IL-4, IL-21	+	• Activate B cells and promote differentiation to antibody-secreting plasma cells
T_H9	IL-4, TGFβ	IL-9, IL-10, IL-21	+	• ↑ Mast cell proliferation and activity • ↑ Eosinophil recruitment • ↑ T_H2 responses and IgE production • Promote lymphocyte recruitment and IFNγ production
T_H2	IL-4	IL-4, IL-5, IL-10, IL-13	+ −	• Direct macrophages toward alternative (immunosuppressive) activation • Direct B cells to produce IgE • Activate eosinophils • ↑ T_H2 differentiation and ↓ T_H1
T_{reg}	IL-2, TGFβ	IL-10, TGFβ	− −	• Suppress macrophage activation • Suppress T_H1 development

NO, nitric oxide; *ROS*, reactive oxygen species.

T_H1 Cells

T_H1 cells are primarily responsible for activating innate immune cells and controlling infections caused by phagocytosed pathogens. T_H1 cells develop in response to

activation of the transcription factors STAT4 and Tbet by the cytokines IL-12 and IFNγ. Activated T_H1 cells function via a combination of cytokine secretion and CD40:CD40L binding to activate phagocytic cells (mainly macrophages) as follows: (1) induce production of nitric oxide and other reactive oxygen species, thus initiating oxidative burst-mediated microbial killing, and (2) up-regulate cell surface expression of MHC molecules and B7 costimulatory molecules to enhance antigen presentation. This form of macrophage activation, which promotes inflammation and effective microbial killing, has been termed *classic* macrophage activation.

T_H2 Cells

T_H2 cells, by contrast, promote "alternative" macrophage activation characterized by the production of antiinflammatory cytokines, IL-10 and transforming growth factor beta (TGFβ). For this reason, T_H2 cells are generally thought of as an antiinflammatory helper T-cell subset. T_H2 cells develop in response to IL-4–mediated activation of the transcription factors STAT6 and GATA-3. The primary antiinfective role of T_H2 cells is to direct mast cells, eosinophils, and the humoral immune response toward control of parasitic infection. These cells also play important roles in promoting IgE-mediated allergic reactions.

T_H17 Cells

T_H17 cells develop in response to activation of the transcription factors STAT3 and RORγt in the setting of multiple cytokines, including IL-1, IL-6, IL-23, and TGFβ. T_H17 cells are often found associated with mucosal surfaces (eg, the gastrointestinal tract) and are likely involved in immunity to mucosal pathogens. They are potently proinflammatory cells and have been implicated in a number of autoimmune and inflammatory conditions.[9,10] Specific functions of T_H17 cells include recruiting leukocytes (primarily neutrophils) to sites of infection, promoting the production of antimicrobial peptides such as defensins, enhancing epithelial barrier function and cytokine production, and enhancing $CD8^+$ T-cell activity.

T Follicular Helper (T_{FH}) Cells

T_{FH} cells are a relatively recently identified T helper cell subset and they primarily reside in and around germinal centers of secondary lymphoid organs.[11] Their development relies on interaction with activated B cells via the inducible costimulatory (ICOS) molecule and activation of the transcription factor BCL-6. T_{FH} cells function within germinal centers to promote B-cell proliferation and immunoglobulin production.

T_H9 Cells

T_H9 cells are another relatively recently identified T helper cell subset and, as the name implies, they are characterized by secretion of the cytokine, IL-9. T_H9 cells may be primarily located in the skin and along mucosal surfaces. Like T_H2 cells, activated T_H9 cells enhance mast cell function, eosinophil recruitment, and IgE production and provide immunity against parasitic infection. They also promote lymphocyte

recruitment and IFNγ production and have been implicated in autoimmune and allergic diseases including eczema, asthma, food allergies, and inflammatory bowel disease.[12,13]

Regulatory T Cells (Treg)

Naturally occurring regulatory T cells (Treg) are an immunosuppressive subset of CD4$^+$ T cells characterized by high expression of the cell surface marker CD25 and diminished expression of the IL-7 receptor, CD127. The transcription factor FOXP3 is required for Treg development and function, and it serves as an additional Treg marker. Treg cells arise in the thymus during T-cell development in response to recognition of self-peptide. Though they constitute a relatively small percentage of the total circulating T-cell population (approximately 5%-10% under normal circumstances), they play an important role in maintaining T-cell tolerance to self-antigens. In the ICU, whereas down-regulation of Treg cells may contribute to autoimmune and allergic disease, pathologic up-regulation of Treg cells have been associated with immune suppression and adverse outcomes in critically ill septic adults. These studies, however, have not been consistent, and whether Treg cells play a role in pediatric sepsis is currently unclear.[14-18]

Additional T-Cell Subtypes

Although the majority of circulating T cells carry T-cell receptors composed of an α and a β chain, a minority of T cells (<5%) contain T-cell receptors composed of a γ chain and a δ chain. These cells are referred to as $\gamma\delta$ T cells. Unlike $\alpha\beta$ T cells, $\gamma\delta$ T cells are not MHC restricted, meaning that they can recognize antigens not bound by MHC molecules. The $\gamma\delta$ T cells also may be activated by nonprotein microbial antigens such as phosphates and lipids as well as heat shock proteins. When activated, $\gamma\delta$ T cells produce inflammatory cytokines, IFNγ, tumor necrosis factor alpha (TNF)α, and IL-17. Because $\gamma\delta$ T cells often reside at epithelial surfaces, it is thought that they serve an important function in the early defense against epithelial microbes.[19]

NKT cells are a second small subset of T cells with distinct function. NKT cells are so named because they carry both natural killer (NK) cell markers (eg, CD 56) and a T-cell receptor. NKT cells function like innate immune cells in that they quickly produce cytokines in response to pathogens. They also respond in an antigen-dependent manner via T-cell receptor recognition of lipid antigens bound to MHC-like molecules called CD1d.[20]

Adaptive Immunity in the Intensive Care Unit

A well-functioning immune response is vital to the resolution of infection, prevention of new infection, and recovery from critical illness. However, as will be reviewed in greater detail in Chapter 105, critical illness is often associated with suppressed immune cell function, which is associated with increased risks of nosocomial infection and mortality.[15,21-24] Although much of the work in critical illness–associated immune suppression has focused on innate immunity, data from septic adults and children suggest that suppressed or down-regulated adaptive

immune responses are also associated with adverse outcomes.[5,15,25] Specifically, multicenter genomic studies of children with septic shock consistently demonstrate down-regulation of genes within adaptive immunity pathways, a pattern that may be exacerbated by corticosteroid use.[25-28] Mechanisms of adaptive immune suppression in septic shock have yet to be fully elucidated. Lymphocyte apoptosis has been long recognized in both adult and pediatric sepsis and likely plays a role in sepsis-induced immune suppression.[29,30] However, other mechanisms may be important as well. As mentioned previously, immunosuppressive regulatory T cells may contribute to sepsis-induced immune suppression, though data to support this mechanism are currently mixed.[14-18] Increased expression of negative costimulatory molecules, CTLA-4 and PD-1, has been demonstrated in animal models of sepsis and in septic adults, and they may represent an additional mechanism for critical illness–associated immune suppression.[4-6,31,32] These pathways may provide future therapeutic targets and are the subject of much ongoing study.

Aside from critical illness–associated immune suppression, the pediatric intensivist often cares for patients whose adaptive immune responses are intentionally suppressed to treat autoimmune disease or to prevent posttransplant organ rejection. Glucocorticoids represent one of the most common immunosuppressants administered in the ICU. Antiinflammatory glucocorticoids, such as methylprednisolone and dexamethasone, potently suppress T-cell function by blocking cytokine production and inducing T-cell apoptosis. Other immunosuppressive medications commonly encountered in the ICU are outlined in Table 102.4. Given the importance of adaptive immune function in the ICU, particularly in the setting of infection, it is likely that immunosuppressive medications may need to be tailored to the unique individual needs of the critically ill patient. Unfortunately, available evidence to guide immunosuppressive medication management in the pediatric intensive care unit is lacking and adult data are limited, with a single report suggesting that rapidly tapering immunosuppression in transplant patients with sepsis and documented severe immune suppression may be beneficial without sacrificing graft survival.[33]

TABLE 102.4

Selected Immunosuppressive Medications Targeting Adaptive Immune Function

Drugs	Mechanism of Action	Select Uses
Polyclonal Antibody Sera		
Antithymocyte globulin	Lymphocyte depletion	Posttransplant induction therapy
Monoclonal Antibodies		
Basiliximab, daclizumab	Prevent T-cell activation and proliferation by blocking the IL-2 receptor (CD25)	Posttransplant induction therapy
Rituximab	Binds CD20 on B-cell surface leading to B-cell lysis	Pretransplant therapy for HLA-sensitized recipients, certain refractory autoimmune diseases, autoimmune cytopenias
Calcineurin Inhibitors		
Cyclosporine, tacrolimus	Inhibit T-cell cytokine production by blocking phosphatase activity of calcineurin	Posttransplant maintenance therapy
mTOR Inhibitors		
Sirolimus, everolimus	Block T-cell proliferation and differentiation by blocking the serine/threonine protein kinase, mTOR	Posttransplant maintenance therapy
Antiproliferative Drugs		
Azathioprine	Converts to purine analog, which competitively inhibits DNA synthesis and blocks proliferation of	Posttransplant maintenance therapy, autoimmune hepatitis

	bone marrow–derived cells	
Mycophenolate mofetil	Inhibits lymphocyte proliferation by inhibiting purine synthesis	Posttransplant maintenance therapy, lupus nephritis
Methotrexate	Inhibits folic acid pathway, which inhibits purine and pyrimidine synthesis	Juvenile idiopathic arthritis, psoriasis, inflammatory bowel disease
Cyclophosphamide	DNA alkylating agent inhibits lymphocyte proliferation	Lupus nephritis, refractory autoimmune disease

In sharp contrast to pharmacologic immunosuppression, cancer immunotherapy is an evolving field that involves augmenting adaptive immune responses in order to treat malignancy. The underlying premise of antitumor immunotherapy involves stimulating immune cell responses and often targeting those responses toward tumor-specific antigens. Although these therapies show early promise in the treatment of relapsed or metastatic disease, some patients experience potentially life-threatening side effects related to immune activation and the associated cytokine storm.[34] These patients often require transition to the intensive care unit for support of hemodynamics and organ function. One example of cancer immunotherapy in pediatrics is the use of the monoclonal antibody, mAB ch14.18, which recognizes the disialoganglioside, GD2, found on neuroectodermal cells and highly expressed on neuroblastoma. In a phase III trial of high-risk neuroblastoma patients, ch14.18 combined with IL-2 and granulocyte-macrophage colony-stimulating factor (GM-CSF) was significantly associated with improved event-free survival compared to standard therapy.[35] At this time, there are multiple ongoing clinical trials evaluating anti-GD2 antibodies either with or without additional immunomodulators for pediatric neuroblastoma.[36] A second example of emerging cancer immunotherapy involves the infusion of autologous T cells that have been genetically modified to express chimeric antigen receptors (CARs) that recognize tumor cell surface markers and are fused to T-cell receptor signaling domains. Clinical studies of CARs in pediatric oncology patients are currently limited, though CARs that recognize the cell surface marker CD19 have shown remarkable promise in early phase I studies of refractory B-cell acute lymphoblastic leukemia (ALL).[37,38] Based on these early successes, it is likely that the role of cancer immunotherapy may continue to expand, carrying with it the potential need for critical care intervention.

Summary

As will be highlighted further in subsequent chapters, attention to maintaining a well-regulated and functional immune response is essential for many of the children cared for in the intensive care unit. The cellular components of adaptive immunity, B cells and T cells, help drive a complex, well-regulated interchange of cellular responses and chemical signaling leading to optimum performance of both innate and adaptive immunity. As attention focuses on maintaining and restoring coordinated, functional immune responses in the intensive care unit, it will be increasingly important for the pediatric intensivist to understand the components of both the innate and adaptive immune systems.

CHAPTER 103

Congenital Immunodeficiency

Troy Torgerson

PEARLS

- Approximately 300 single gene defects have now been associated with specific immunodeficiencies.
- Chronic granulomatous disease is the most frequently diagnosed phagocytic cell immune defect. The most common form is X-linked, caused by mutations in the *CYBB* gene and accounting for approximately two-thirds of all CGD patients. All mutations affect the formation or function of the NADPH oxidase complex on neutrophil phagolysosomes.
- X-linked agammaglobulinemia is the prototypic B-cell disorder. It is caused by mutations in the Bruton's tyrosine kinase gene (BKT), required for the maturation of B-cell precursors in the bone marrow. Mutations in BTK cause an arrest of B-cell development at the pre–B-cell stage, leading to virtual absence of circulating B cells in the peripheral blood.
- Common variable immunodeficiency (CVID) is a heterogeneous disorder that is likely caused by a variety of molecular mechanisms that ultimately lead to a similar clinical phenotype.
- With IgG supplementation, this group of patients has a relatively benign course with long-term survival that is not unlike the normal population.
- Selective IgA deficiency is common in the general population, and patients with selective IgA deficiency have no apparent symptoms that can be directly linked to their immune defect. In patients who are truly IgA deficient, sensitization to IgA itself can be a problem, leading to anaphylactic reactions during infusions of blood products.
- Deletions within the 22q11.2 region of the long arm of chromosome 22 have been associated with various clinical syndromes including DiGeorge syndrome (DGS), velocardiofacial syndrome (VCFS), conotruncal anomaly face syndrome (CTFS), and CATCH22 syndrome.
- The characteristic T-cell lymphopenia of DiGeorge syndrome is thought to arise primarily from the absence of adequate thymic tissue. Both $CD4^+$ and $CD8^+$ T cells are low; however, $CD8^+$ T-cell numbers tend to be more affected in most

patients.

- Severe combined immune deficiency (SCID) is among the most severe immunodeficiencies and is made up of a variety of related disorders caused by mutations in more than 20 different genes. All forms of SCID have deficiency of one or more subsets of T cells. In many cases, there are no circulating T cells.
- Adenosine deaminase (ADA) deficiency was the first molecularly defined immunodeficiency with discovery of patients with SCID. When adenosine deaminase activity is impaired or absent, intracellular levels of deoxy-ATP (dATP) rise to interfere with ribonucleotide reductase and DNA synthesis and repair are slowed and lymphocyte apoptosis increased.
- X-linked (IPEX) syndrome involves regulatory T-cell deficiency, and phenotypically includes immune dysregulation, polyendocrinopathy, and enteropathy. IPEX is caused by mutations in the *FOXP3* gene located on the X chromosome, which encodes a key transcription factor that is required for the generation of functional regulatory T cells (Treg). In the absence of *FOXP3,* patients present with severe, early-onset, systemic autoimmunity.
- Ataxia telangiectasia (AT) is a disorder associated with progressive neurologic decline, immunodeficiency, and propensity to malignancy. It is caused by autosomal recessive mutations in the *ATM* gene, which encodes a serine/threonine kinase that acts together with the NBS1 protein as one of the major sensors of double-stranded DNA breaks in the cell. In the absence of functional ATM or NBS1, cells have a marked sensitivity to ionizing radiation.

Introduction

The immune system plays a vital, integral role in human health and disease because of its interactions with every other organ system in the body. In one way or another, it plays particularly important roles in diseases that often affect patients admitted to pediatric ICUs (PICUs) including those with severe infections and sepsis, severe autoimmunity, malignancies, inflammatory disorders such as hemophagocytic lymphohistiocytosis, asthma, and type I diabetes with diabetic ketoacidosis. This chapter focuses particularly on immunologic disorders that are most likely to be encountered in the PICU setting.

The normal and pathogenic roles of each component of the immune system in humans have been significantly clarified by the study of patients with primary immunodeficiency disorders (PIDDs), a group of clinical syndromes originally described in patients with marked susceptibility to particular types of infection. This group of disorders has now expanded to include more than 150 clinically defined entities that span the full spectrum of immune dysfunction ranging from virtually absent immune responses to overwhelming, uncontrolled autoimmunity and susceptibility to malignancy.[1] Many of these disorders are inherited, and approximately 300 single gene defects have now been associated with specific immunodeficiencies. Through these efforts, it has also become evident that mutations in different genes can lead to a similar clinical phenotype. For example, defects in more than 20 different genes have now been associated with a clinical phenotype of severe combined immune deficiency (SCID).[2] Consequently, it has become the practice to refer to disorders by their molecular defect, either in

combination with or in lieu of their clinical name or eponym (ie, "ADA-deficiency" or "ADA-SCID" rather than just "SCID"). This practice is followed here.

Basic Framework for Understanding the Immune System

In order to provide structure to facilitate an understanding of the immune system, the diseases associated with immune dysfunction, and how these should be recognized, evaluated, and treated, it is worthwhile to establish a basic framework (see also Chapters 101 and 102). In this framework, the immune system can be divided into four major compartments: complement, phagocytes, B cells and antibodies, and T cells. Approximately 300 single gene defects have now been associated with specific immunodeficiencies. The complement and phagocyte compartments are part of the "innate" arm of the immune system, which responds in a similar way each time a particular pathogen is encountered but does not develop immunologic memory (see Chapter 101). In contrast, the B-cell and T-cell compartments comprise the "adaptive" arm of the immune system, which learns each time a pathogen is confronted and develops memory so that responses to pathogens encountered previously can be remembered, thus facilitating a more rapid, effective response (Table 103.1) (see Chapter 102). Many immunodeficiency disorders are caused by a defect in only one compartment of the immune system while others are "combined" immunodeficiencies with defects in both the B- and T-cell compartments. In general, defects in each compartment of the immune system are associated with susceptibility to particular types of infections dictated by the dominant role of that compartment in human immunity. In addition, each immunodeficiency typically has unique clinical and laboratory features that differentiate it from other disorders, thus making it possible to predict which disorder a patient may have on the basis of clinical and laboratory findings (Table 103.2).

TABLE 103.1

Symptoms Associated With Defects in Each Immune Compartment

	Complement	**Phagocytes**
INNATE	Invasive infections with encapsulated bacteria (eg, *S. pneumoniae, H. influenzae*) Recurrent, invasive *Neisserial* infections Autoimmunity (lupus, glomerulonephritis) Hereditary angioedema Atypical hemolytic uremic syndrome (HUS)	Skin and soft tissue abscesses, boils, and lymphadenitis Infections with catalase-+ organisms (eg, *S. aureus, Serratia, Aspergillus*) Poor wound healing Chronic gingivitis and periodontal disease Mucosal ulcerations, colitis Omphalitis/delayed separation of the umbilical cord
	B Cells/Antibodies	**T Cells**
ADAPTIVE	Recurrent bacterial sinopulmonary infections (otitis media, sinusitis, bronchitis, and pneumonia) Unexplained bronchiectasis Chronic or recurrent gastroenteritis (eg, *Giardia, Cryptosporidium, Enterovirus*) Echovirus encephalomyelitis	*Pneumocystis jirovecii* pneumonia Recurrent, severe, or unusual viral infections (eg, CMV, EBV, adenovirus, papillomavirus) Invasive fungal or mycobacterial infections GvHD (rash, abnormal LFTs, chronic diarrhea) Failure to thrive

TABLE 103.2

Cellular Phenotype and Molecular Defects in Severe Combined Immune Deficiency (SCID)

	Disorder	Gene	Inheritance	Features
$T^-B^-NK^-$	Adenosine deaminase deficiency	*ADA1*	AR	Costochondral abnormalities, neonatal hepatitis
	Purine nucleotide phosphorylase deficiency	*PNP*	AR	Progressive neurologic decline
	Reticular dysgenesis	*AK2*	AR	SCID phenotype + Neutropenia
$T^-B^-NK^+$	RAG1 deficiency	*RAG1*	AR	
	RAG2 deficiency	*RAG2*	AR	
	Artemis deficiency	*DCLRE1C*	AR	Radiosensitivity
	DNA-PKcs deficiency	*PRKDC*	AR	Radiosensitivity
	DNA Ligase IV deficiency	*LIG4*	AR	Radiosensitivity, microcephaly, growth retardation
	Cernunnos/XLF deficiency	*NHEJ1*	AR	Radiosensitivity, microcephaly, growth retardation
$T^-B^+NK^-$	Common γ chain deficiency	*IL2RG*	XL	
	JAK3 deficiency	*JAK3*	AR	
	CD45	*PTPRC*	AR	Some NK cells may be present
$T^-B^+NK^+$	IL-7 Receptor-α (CD127) deficiency	*IL7RA*	AR	
	DiGeorge syndrome	*22q11.2 del*	AD	Hypoparathyroidism, cardiac defects, dysmorphic facies
	CHARGE syndrome	*CHD7*	AD	Multiple congenital anomalies—clinical complex of CHARGE syndrome
	CD3δ deficiency	*CD3D*	AR	
	CD3ε deficiency	*CD3E*	AR	
	CD3γ deficiency	*CD3G*	AR	
	CD3ζ deficiency	*CD3Z*	AR	
	P56Lck deficiency	*LCK*	AR	
	Coronin-1A deficiency	*CORO1A*	AR	Lymphadenopathy
$T^{+/-}B^+NK^+$	MHC class I deficiency	*TAP1*	AR	$CD8^+$ T cells are typically decreased but not absent, recurrent respiratory infections

AD, autosomal dominant; *AR*, autosomal recessive; *XL*, X-linked recessive.

Modified from Cossu F. *Ital J Pediatr* 2010;36:76.

Compartment 1: Complement

The complement system consists of a series of proteins that are present in the plasma and become activated on encountering pathogens. The complement cascade is activated via three major mechanisms (see Fig. 103.1): (1) the *Classical Pathway*, which is initiated by antigen/antibody complexes; (2) the *Alternative Pathway*, which is initiated directly by bacterial cell wall components; and (3) the *Lectin Pathway*, which is initiated by carbohydrate moieties present on bacteria. Activation of early complement components initiates a cascade of protein cleavage and activation events that ultimately lead to formation of the Membrane Attack Complex (MAC) consisting of complement proteins C5, 6, 7, 8, and 9. A number of regulatory proteins including C1 inhibitor, factor H, factor I, MCP, and CD59 control complement activation at multiple levels, thereby preventing inappropriate complement fixation.

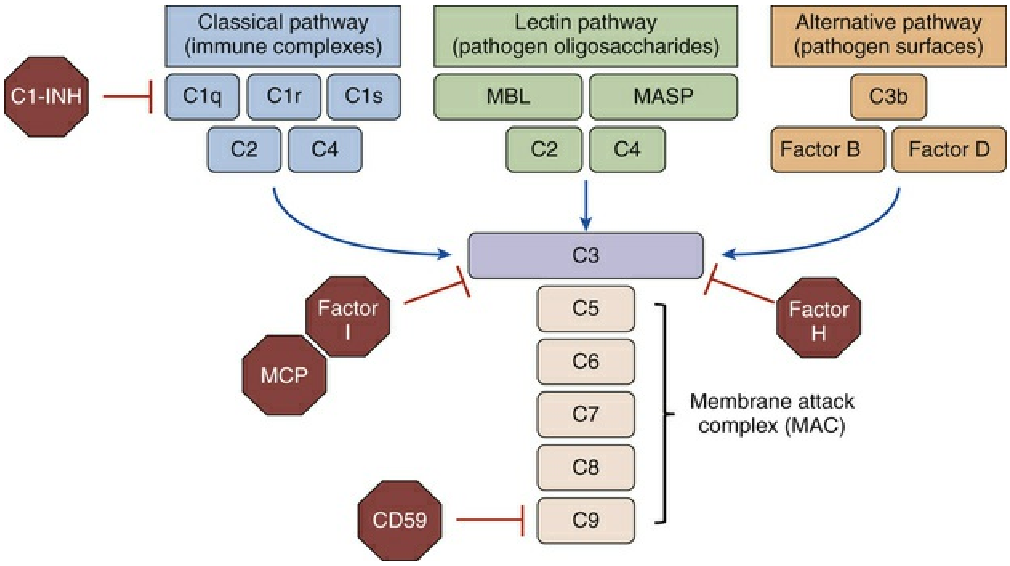

FIG. 103.1 The complement cascade is activated via three major mechanisms: (1) *classical pathway*, which is initiated by antigen/antibody complexes; (2) *alternative pathway*, which is initiated directly by bacterial cell wall components; and (3) *lectin pathway*, which is initiated by carbohydrate moieties present on bacteria.

Complement deficiencies make up only a small portion (~2%) of all primary immune deficiencies, but the consequences can be devastating for affected patients.[3] Defective activation of the entire complement cascade can be caused by the absence or dysfunction of only 1 of more than 20 complement proteins. The proteins most often affected are C2, C3, and C4.[4]

Clinical Presentations

Patients with defects in early complement components in the classical pathway (C1-C4) typically present with recurrent, invasive infections caused by encapsulated organisms (particularly *Streptococcus pneumoniae*) or with symptoms of autoimmunity (lupus or glomerulonephritis). Patients with defects in the late complement components (C5-C9) that are involved in formation of the membrane attack complex typically present with recurrent or severe *Neisseria* infections.[4] Patients who lack functional C1 esterase inhibitor have hereditary angioedema in which allergic or mechanical stimuli can trigger massive, localized, severe attacks of edema that can be life threatening if they involve the airway. Patients with defects in complement regulatory proteins (Factor I, Factor H, and MCP) are at risk of developing familial hemolytic uremic syndrome (HUS) and age-related macular degeneration.[5-7]

Compartment 2: Phagocytes

One of the major roles of phagocytic cells (neutrophils and macrophages) is to continuously survey the body for signs of infection. Upon sensing an infection, they migrate from the circulation into the tissues toward the site of the infection, where they ingest both opsonized and nonopsonized pathogens and debris. The ingested material is processed, and fragments of digested proteins are loaded into class II MHC molecules that are presented at the cell surface, where they can be recognized

by cells of the adaptive immune system. Phagocytes that ingest pathogens and debris can either remain at the site of infection or migrate back to local draining lymph nodes to present antigen. Phagocytic disorders can occur as a result of one of three types of defects: (1) a lack of phagocytes (congenital neutropenia); (2) abnormal phagocyte migration (leukocyte adhesion deficiency and WHIM syndrome); (3) inability of phagocytes to process or degrade material or organisms that have been ingested (chronic granulomatous disease).

Clinical Presentations

Because of the role that phagocytes play in controlling bacterial and fungal pathogens, patients with phagocytic defects often present with infections and abscesses of skin, deep tissues, and organs caused by bacteria or fungi. Symptoms can include boils or cellulitis with or without pus, lymphadenitis, pneumonia, delayed shedding of the umbilical cord, omphalitis hepatic abscesses, gastrointestinal disorders, gingivitis, unexplained fever, malaise, and fatigue. The onset of symptoms of phagocyte disorders is typically in infancy or early childhood.

Compartment 3: B Cells and Antibodies

The predominant role of B cells in the immune system is to make antibodies (immunoglobulins) in response to antigen challenge (eg, pathogens, vaccines). The absence of functional antibodies causes susceptibility to bacterial and viral infections. Antibody deficiency can occur in one of three different ways: (1) hypogammaglobulinemia or low levels of one or more immunoglobulin classes (IgG, IgA, IgM, or IgE) occurring as a result of decreased antibody production, which may be associated with specific genetic defects; (2) hypogammaglobulinemia as a result of excessive antibody loss, typically through the kidneys as proteinuria or through the gut as protein-losing enteropathy; (3) functional antibody deficiency, in which immunoglobulin levels are normal but the immunoglobulin lacks the quality required to bind and opsonize pathogens.

Clinical Presentations

Patients who lack sufficient levels of functional antibody present with recurrent bacterial sinopulmonary infections (sinusitis, otitis media, bronchitis, and pneumonia). In addition, due to a lack of IgA, patients may develop bowel infections caused by microorganisms such as *Giardia* or *Cryptosporidium* that are often only modestly pathogenic to normal individuals. In addition to these symptoms, patients with certain antibody-deficiency disorders have characteristic clinical features that can provide clues to the specific diagnosis. These are discussed in more detail later in the chapter.

Compartment 4: T Cells

A handful of disorders are characterized by the absence of T cells only. It is much more common, however, for T-cell deficiency or dysfunction to be part of a more extensive “combined” immune deficiency accompanied by defects in B cells and/or NK cells. Identification of a number of new genetic defects over the past decade has dramatically expanded the spectrum of this group of disorders. Some are typified by

significant, generalized T-cell lymphopenia while others are characterized by the absence or dysfunction of one or more specialized subsets of T cells.

Clinical Presentations

Patients who have a generalized absence of functional T cells are susceptible to unusual or severe viral infections caused by viruses including cytomegalovirus (CMV), Epstein-Barr virus (EBV), and adenovirus. Patients are also susceptible to fungal infections caused by organisms such as *Pneumocystis jiroveci,* which are not pathogenic in normal individuals but commonly cause pneumonias in this group of patients. In parts of the world where the attenuated mycobacterium bacille Calmette-Guérin (BCG) is used as a vaccine, patients with T-cell deficiency often develop invasive and disseminated mycobacterial infection that is often fatal. A lack of functional T cells also makes it impossible to provide adequate T-cell help to allow B cells to undergo normal immunoglobulin class-switching, so patients usually have functional antibody deficiency as well. In addition, patients with T-cell deficiencies frequently have symptoms of autoimmunity including diarrhea (secondary to autoimmune enteropathy), cytopenias (autoimmune hemolytic anemia [AIHA]), and idiopathic thrombocytopenic purpura (ITP), and hepatitis.

Specific Disorders Likely to Be Encountered in Pediatric ICU

Specific Disorders: Complement

C1 Inhibitor Deficiency

Deficiency of C1 esterase inhibitor is the cause of hereditary angioedema (HAE). HAE is an autosomal dominant disorder that affects 1 in 10,000 to 1 in 50,000. Unlike many of the other early-complement component deficiencies, absence of C1 esterase inhibitor (C1-INH) does not lead to increased risk for infection. Instead, this protein regulates the activity of kallikrein, which causes bradykinin release as a result of cleavage of high-molecular-weight kininogen (HMWK). In the absence of C1-INH, minor irritants such as the menstrual cycle, dental procedures, or surgery can cause unabated production of bradykinin and other mediators of vascular permeability, leading to rapid swelling of the soft tissues (angioedema), severe abdominal pain, and at times, acute obstruction of the airway. Diagnosis of C1-INH deficiency can be made by measuring the level and function of the C1 inhibitor in blood. Patients with C1-INH deficiency also commonly have low-complement C4 levels as well, which can provide an additional clue to the diagnosis. Effective treatments are now available for HAE, including purified C1 esterase inhibitor, a kallikrein inhibitor, and a bradykinin B2 receptor antagonist.[8-10] These therapies can be lifesaving during an acute attack. Because of their expense, they are often administered at the beginning of an attack to abort symptoms rather than prophylactically to prevent the onset of an attack. Unlike typical anaphylaxis, which responds well to epinephrine injections, patients with C1-INH deficiency typically exhibit only modest responses to epinephrine.

Early Classical Pathway Defects (C1, C2, C3, C4)

Patients with defects in early classical complement pathway proteins (C1-C4) are susceptible to invasive infections with encapsulated organisms. *Streptococcus pneumoniae* and *Haemophilus influenzae* are particularly fulminant pathogens in these patients. The infectious susceptibility is compounded by functional antibody deficiency in some patients. Among these disorders, C2 deficiency is the most common complement component deficiency associated with susceptibility to infections, occurring in approximately 1 of 20,000 people. In addition to the dramatic infectious susceptibility, patients with defects in these early classical pathway proteins are at high risk of developing autoimmunity (systemic lupus erythematosus and/or glomerulonephritis). As an example, in patients with homozygous C2 deficiency, approximately 50% of patients develop lupus or glomerulonephritis.[11] The autoimmunity caused by complement deficiency is difficult to treat because no amount of immune suppression will control the underlying pathophysiologic mechanism of disease. There are a growing number of anecdotal reports and small case series in which severe lupus caused by complement deficiency was effectively treated with intermittent infusions of fresh frozen plasma, which contains active complement proteins.

Late Pathway—Membrane Attack Complex Defects (C5, C6, C7, C8, C9)

Patients with defects in the late complement pathway proteins that form the membrane attack complex (C5-C9) are susceptible, almost exclusively, to invasive infections with *Neisseria* species. These patients have a 7000- to 10,000-fold higher risk of developing meningococcal disease than the normal population.[12] On the basis of this, some have suggested that every patient who develops *Neisseria meningitides* sepsis should be screened for complement deficiency using a CH50 test. Doing this may be cost prohibitive in many settings, but there is general consensus that patients who have recurrent invasive infections caused by *N. meningitides* should definitely be screened for complement deficiency because of the high incidence of recurrence (40%-50%) in these individuals.

Complement Regulatory Protein Defects (Factor H, Factor I, MCP)

The complement cascade is regulated at multiple levels by a series of regulatory proteins that prevent indiscriminate activation that could lead to inappropriate inflammation and tissue destruction (Fig. 103.2). Because all complement pathways converge on the activation of C3 before initiation of the membrane attack complex, the cell-bound regulatory proteins that deactivate the cleaved C3 are among the most important functionally. Mutations in Factor H, Factor I, or MCP allow the complement cascade to be more readily activated and lead to susceptibility to atypical HUS, which may be triggered even in the absence of bacterial infection. Unfortunately, there are no straightforward functional tests available to detect abnormalities in these regulatory proteins, so gene sequencing is required to make the diagnosis. In patients with uncontrolled HUS, therapeutic monoclonal antibodies that bind to C5 and prevent formation of the membrane attack complex have been used to control disease.

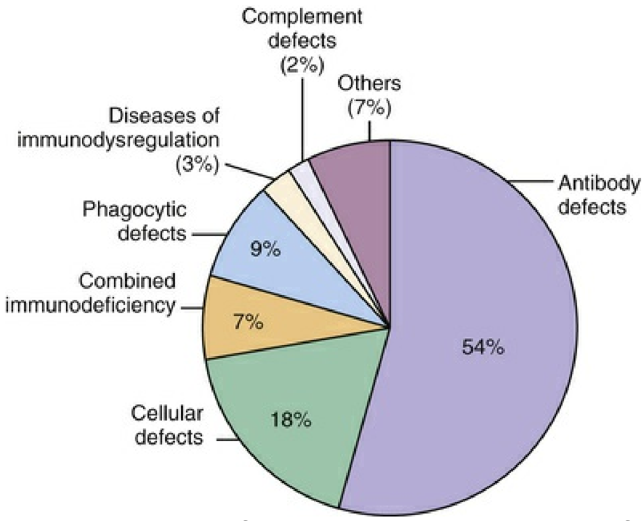

FIG. 103.2 Distribution of the major primary immunodeficiency disorders. (Data from the Jeffrey Modell Foundation Survey, 2009.)

Specific Disorders: Phagocytes

Severe Congenital Neutropenia

Patients with severe congenital neutropenia (SCN) typically present early in life with recurrent infections including invasive soft tissue infections and sepsis. Staphylococcal infections are particularly problematic. Mutations in five different genes have now been associated with severe congenital neutropenia: *ELANE,* which is inherited in an autosomal dominant manner, causes increased myeloid cell apoptosis and can present either with SCN or with a cyclic neutropenia phenotype. *GFI1,* which is also inherited in an autosomal dominant manner, causes defective myeloid cell differentiation. *HAX1,* which is inherited in an autosomal recessive manner, is associated with increased myeloid cell apoptosis and is the cause of the classic "Kostmann" neutropenia syndrome. *G6PC3,* which is inherited in an autosomal recessive manner, causes excessive myeloid cell apoptosis and is associated with a variety of other congenital defects including cardiac, urogenital, endocrine, auditory, and facial anomalies. *WAS,* in which specific activating mutations in the CDC42 binding domain of the WASp protein are inherited in an X-linked recessive manner, leads to abnormal and dysregulated actin polymerization that causes defective neutrophil chemotaxis and increased apoptosis.[12]

Clinical management of severe congenital neutropenia involves a heightened suspicion for infections and aggressive treatment if these arise. Treatment of acute infections may require antibiotics combined with G-CSF to increase neutrophil counts. Despite there being little evidence specifically in SCN supporting the use of prophylactic antibiotics, extrapolation from data in leukemic patients with neutropenia suggests a benefit, so this is used in most patients. Prophylactic, long-term therapy with G-CSF is typically used only in those patients who have recurrent, severe bacterial infections in spite of antibiotic prophylaxis or in patients with fungal infections. Bone marrow transplantation is effective in SCN, although there is little to no reported experience in those genetic disorders that are more rare such as G6PC3 deficiency.

Leukocyte Adhesion Deficiency

Leukocyte adhesion deficiency (LAD) is caused by the absence of functional adhesion receptors that are required for the migration of phagocytes from the circulation into the tissues. The characteristic clinical features of LAD include recurrent skin and soft tissue infections, which often lead to development of cutaneous boils or deep ulcers despite there being highly elevated peripheral blood leukocyte counts. Interestingly, the inability of leukocytes to migrate to these sites of infection leads to an absence of pus in the lesions, which can be a useful diagnostic clue. Wound healing is also compromised, and patients typically have marked gingivostomatitis. Three forms of LAD have been described: *LAD-I,* the most common form of LAD, is caused by mutations in the *ITGB2* gene encoding the β2-integrin CD18. Mutations cause an absence of the CD11/CD18 integrin complex on the surface of leukocytes, which can be readily discerned by flow cytometry. *LAD-II* is caused by mutations in the *SLC35C1* gene encoding the GDP-fucose transporter. These mutations cause defective expression of Sialyl Lewis X (sLe^X), a fucose-containing ligand on neutrophils. sLe^X is the ligand for E- and P-selectins, which are expressed on the surface of cytokine-activated endothelial cells and allow neutrophil rolling. As a result of the fucose defect, all patients with LAD-II also have the rare Bombay blood group, which is a useful diagnostic test for suspected LAD-II. *LAD-III* is caused by mutations in the *FERMT3* gene that encodes kindlin-3, a coactivator that is required for activation and function of β1-, β2-, and β3-integrins. Absence of functional kindlin-3 leads to dysfunction of CD18 and causes an LAD phenotype (see LAD-I earlier). In addition, patients with LAD-III also have a Glanzmann-type bleeding disorder resulting from dysfunctional integrin-mediated aggregation of platelets.[13]

Patients with LAD-I and LAD-III typically present in childhood and often have a severe course with early mortality, whereas patients with LAD-II are often milder and may live into adulthood. Treatment of leukocyte adhesion deficiency can be more complicated than some of the other phagocytic disorders because in addition to aggressively treating infections with antibiotics, active soft tissue infections may require recurrent donor white cell infusions of functional neutrophils in order to clear the infection. Because the primary defects of LAD are intrinsic to hematopoietic cells, bone marrow transplantation can be curative.[14-16]

WHIM Syndrome

Warts, hypogammaglobulinemia, recurrent bacterial infections, and myelokathexis (retention of neutrophils in the bone marrow) (WHIM) syndrome is caused by autosomal dominant mutations in CXCR4, the receptor for the chemokine CXCL12 (SDF-1). Patients with WHIM syndrome typically present in childhood with recurrent bacterial otitis media, sinusitis, bronchitis, pneumonia, and cellulitis. The bacterial susceptibility is a result of the combination of hypogammaglobulinemia and neutropenia. In addition to bacterial infections, patients with WHIM have a particular susceptibility to papillomavirus infections, which can be severe and lead to early malignancy. The mechanisms that underlie the viral susceptibility are not entirely understood but are thought to possibly be intrinsic to the epithelial cells. In the hematopoietic system, CXCL12 causes homing of cells to the bone marrow and controls release of these cells from the marrow. Neutrophils and lymphocytes from

patients with WHIM have an increased chemotactic response to CXCL12, suggesting that the neutropenia and lymphopenia observed in WHIM are the result of inappropriate cell retention in the marrow.[17] Treatment with G-CSF or GM-CSF can normalize the neutrophil counts, although these often cause significant bone pain at the doses required.[18] Recent studies using the CXCR4 antagonist plerixafor in adults with WHIM syndrome have shown promise for improving neutrophil counts by mobilizing neutrophils from the bone marrow.[19,20] Antibiotics and immunoglobulin replacement can significantly reduce the risk of bacterial infections. There is little reported experience regarding bone marrow transplantation for WHIM, although anecdotal evidence suggests that it may correct the neutropenia and hypogammaglobulinemia but may not alter the papillomavirus susceptibility.[21]

Chronic Granulomatous Disease

Chronic granulomatous disease (CGD) is the most frequently diagnosed phagocytic cell immune defect. The most common form is X-linked, caused by mutations in the *CYBB* gene and accounting for approximately two-thirds of all CGD patients. The remaining forms, caused by mutations in the *CYBA, NCF1, NCF2,* or *NCF4* genes, are all autosomal recessive. All mutations affect the formation or function of the NADPH oxidase complex on neutrophil phagolysosomes. The NADPH oxidase is required to generate a burst of reactive oxygen species in response to phagocytosis of pathogens. Reactive oxygen species activate proteases in the phagolysosomes that destroy ingested bacteria. In CGD, the oxidative burst cannot be generated, leading to defective processing of ingested organisms and an inability to appropriately eliminate bacterial and fungal pathogens. Catalase-positive organisms including *Staphylococcus* species, *Aspergillus* species, *Burkholderia cepacia, Serratia marcescens,* and others are the most common pathogens. The most common types of infection at presentation are pneumonia, lymphadenitis, cellulitis, and hepatic abscesses (particularly with *Aspergillus* sp.). The most common cause of premature death is *Aspergillus* infection.[22] In addition to the infectious susceptibilities of CGD, a substantial percentage of patients struggle with inflammatory complications that are common to this disorder, including an inflammatory colitis that occurs in approximately 40%, hepatic dysfunction, gingivitis, and others.

Treatment of CGD revolves around aggressive management of acute infections followed by prophylaxis against future infections using a combination of daily antibiotic (typically trimethoprim-sulfamethoxazole), daily antifungal (typically itraconazole), and thrice-weekly interferon-γ injections. This combination has dramatically improved outcomes in CGD; however, despite appropriate use of this regimen, some patients ultimately have increasing symptoms that lead to a decline in survival beginning in the late-teens or early 20s. The prospects for long-term survival appear to be correlated with the amount of residual oxidative burst activity that can be generated by a particular patient's phagocytes.[23] This has led to a renewed interest in bone marrow transplantation for CGD, which has been quite successful in the modern era, likely due to improved antimicrobials and transplant conditioning regimens with reduced toxicity. Many now recommend that for patients who have mutations that severely impact oxidative burst activity, bone marrow transplant should be considered preemptively, early in life before patients develop comorbidities.[24]

Specific Disorders: B Cells and Antibodies

X-Linked Agammaglobulinemia

X-linked agammaglobulinemia (XLA) is the prototypic B cell disorder. It is caused by mutations in the Bruton's tyrosine kinase *(BTK)* gene. BTK is a cytoplasmic tyrosine kinase and is required for the maturation of B-cell precursors in the bone marrow.[25] Mutations in BTK therefore cause an arrest of B-cell development at the pre–B-cell stage leading to virtual absence of circulating B cells in the peripheral blood. Mutations that only partially interfere with the enzymatic function of BTK have also been described and are associated with milder forms of the disease that only have defects in generation of specific antibody responses.

XLA is typically suspected in male patients with recurrent bacterial sinopulmonary infections and B-cell lymphopenia. Other infections that occur relatively frequently in patients with XLA before the initiation of IgG replacement therapy include skin infections (furunculosis, pyoderma, and cellulitis) and sepsis. The diagnosis can be confirmed either by identifying a mutation in the *BTK* gene or demonstrating absence of the BTK protein in monocytes or platelets. A positive family history suggestive of an X-linked recessive mode of inheritance increases the suspicion for XLA. It is uncommon for patients with XLA to develop symptoms in the first months of life because newborns are protected from most infections by transplacentally acquired maternal IgG. There are few distinguishing physical features of XLA that can provide clues to the diagnosis, but absence of visible tonsils or adenoids (by physical examination, radiograph, or CT scan) is a useful clue.

In addition to the common sinopulmonary pathogens, patients with XLA are also susceptible to infections by particular opportunistic organisms that are more rare and fastidious, which can cause unusual clinical syndromes. For example, *Helicobacter cinaedi* can cause a syndrome of dermatomyositis and cellulitis that presents with cutaneous ulcerations, particularly on the lower legs.[26,27] The organism can sometimes be recovered from the blood but is fastidious and difficult to culture using usual methods. The ability to culture the organism and evaluate its antibiotic sensitivity is crucial since in many cases it is frequently resistant to various antibiotics. A combination of antibiotics is often necessary to effectively clear the infection.[28] Similarly, *Mycoplasma* species, including *M. hominis,* can cause lung, abdominal, or bone infections that are remarkably hard to eradicate and *Ureaplasma urealyticum* infections are a rare cause of arthritis, urethritis, and pneumonia.[29]

Before the widespread use of IgG supplementation in these patients, opportunistic viral infections, particularly with viruses that require an extracellular phase, were especially problematic. For example, Echovirus encephalitis was estimated to be the cause of death in ~10% of boys with XLA in the 1970s, but that number has fallen dramatically with aggressive use of IgG supplementation. There continue to be rare cases of Echovirus encephalitis in patients with XLA, even in those on adequate IgG replacement therapy, but these are thought to be caused by viral strains for which there may not be high antibody titers in the particular IgG preparation being used.[30,31] Similarly, a mink Astrovirus strain was recently identified by deep sequencing from the brain of an XLA patient who developed a neurodegenerative disorder as a teen.[32] Interestingly, he had lived next to a mink farm as a child but was started on immunosuppression early in his teens for inflammatory bowel disease, which may have allowed the virus to escape control. Lastly, infections with vaccine-

strain poliovirus were pathogenic in undiagnosed patients with XLA who were immunized with the live-viral vaccine after transplacentally acquired maternal antibody had waned. The shift from live attenuated to killed poliovirus for immunization has essentially eliminated new cases.

Hyperimmunoglobulin M Syndromes

Under normal circumstances, binding of antigen to cell surface IgM on naïve B cells induces activation of the B cell. The antigen that is bound to surface IgM on the B cell is ingested and proteolytically digested. Antigenic peptide fragments are displayed on the B-cell surface in MHC class II molecules. Antigen-specific T cells then engage the B cell via MHC II/TCR interactions. Once engaged, the activated helper T cell (Th) provides additional costimulatory signals to the B cell that are critical to promote immunoglobulin class-switching from IgM to IgG, IgA, and IgE. The most important of these costimulatory signals comes via the interaction of CD40 ligand on activated T cells with CD40 on B cells. Activation of the B cell through CD40 and cytokines that are secreted by the helper T cell cause it to undergo class-switch recombination (CSR), during which the μ-heavy chain gene segment within the immunoglobulin gene is replaced by either a γ, α, or ε gene segment. This is accomplished by nicking and double-strand breakage of the DNA in the immunoglobulin heavy-chain locus, which requires a series of enzymatic steps that involve activation-induced cytidine deaminase (AID), uracil DNA glycosylase (UNG), and others. Genetic defects that affect CD40 ligand (CD40L), CD40, AID, or UNG can therefore prevent class-switch recombination, thus thwarting the B cells' ability to make significant amounts of any antibody isotype besides IgM.

The overwhelming majority of patients with hyper-IgM syndrome have the X-linked form caused by X-linked recessive mutations in CD40 ligand (CD40L/CD154), which is encoded by the *CD40L* gene on the X chromosome.[33] CD40L and its receptor CD40 are members of the tumor necrosis factor (TNF) superfamily of ligands and receptors. In lymphocytes, CD40L is expressed only on activated T cells but is also expressed on platelets where its role is unknown. Affected boys may present with recurrent bacterial sinopulmonary infections caused by low IgG, IgA, and IgE, while IgM is normal or elevated. In addition to the usual bacterial pathogens, patients with CD40L mutations also demonstrate unique susceptibilities to fungal infections, particularly *Pneumocystis jirovecii* (PJ), which causes pneumonia, and to a protozoan, *Cryptosporidium parvum* (CP), which causes bowel infections. B lymphocytes are present, and T-cell numbers are generally normal. In almost all cases, the diagnosis can be made by using flow cytometry to evaluate the expression and function of the CD40L protein on activated T cells. Expression is evaluated using antibodies specific to the CD40L protein, and the function is evaluated by measuring the binding of a CD40-Ig heavy chain fusion protein to the expressed CD40L. Gene sequencing can then be performed in order to identify a specific mutation.

The susceptibility to *Pneumocystis* and possibly other fungal pathogens has been somewhat of a puzzle because patients do not have other signs of a significant cellular immune defect, such as severe or recurrent viral infections. Interestingly, the susceptibility to PJ pneumonia appears to go away in most patients by the age of 5. PJ pneumonia is almost always diagnosed by staining bronchoalveolar lavage fluid for the presence of the organism. PJ pneumonia can be readily prevented by prophylactic trimethoprim-sulfamethoxazole administration, and active disease is

amenable to treatment using higher doses of the same drug. Recent data have suggested that the fungal susceptibility in CD40L deficiency may be a result of defective CD40L signaling into dendritic cells and monocytes that express CD40.[34]

Cryptosporidium parvum (CP) bowel infections are more difficult to diagnose and manage in patients with CD40L deficiency. CP may cause abdominal pain, bloating, diarrhea, malabsorption, and weight loss. It may require multiple stool samples to identify the oocysts, and occasionally the diagnosis can only be made on endoscopically obtained biopsy specimens. Treatment with paromomycin or nitazoxanide can clear the infection, although prolonged courses are typically needed in hyper IgM patients and treatment failures are not uncommon. CP infections can result in chronic inflammation of the gut and biliary tree, which seems a likely contributor to the high incidence of bile duct cancers seen in these patients.[35,36]

Treatment involves the use of IgG replacement therapy combined with prophylactic antibiotics for prevention of PJP at least until the age of 5. The role of bone marrow transplantation for CD40L deficiency is still being evaluated. Even though a number of patients have undergone successful bone marrow transplantation, the role of BMT remains somewhat controversial in this disease, although in patients with ongoing CP infection, the prognosis for the patients who develop bile duct disease is so poor that the risks of transplantation are well justified.[37,38]

CD40 deficiency is clinically similar to CD40L deficiency. It is inherited as an autosomal recessive defect that has been described primarily in two cohorts from Italy and the Middle East. It results in a syndrome that is almost identical to CD40L deficiency in which both sexes are affected.[39]

Autosomal recessive mutations in AID and UNG also cause a hyper-IgM phenotype, but it tends to be milder than either CD40L or CD40 deficiency, likely because the defect is limited to B cells, whereas CD40L/CD40 signaling plays a role in other cell types including dendritic cells and monocytes.[40,41] Patients with AID or UNG typically live into adulthood and do not demonstrate the same susceptibility to PJ pneumonia and CP bowel infections. Patients with mutations in AID do, however, have a significant propensity to develop autoimmunity affecting various organ systems. Patients are typically treated with IgG replacement therapy and antibiotics for acute infections. There are no reports of bone marrow transplantation for AID or UNG deficiency.

Common Variable Immunodeficiency Syndromes

Common variable immunodeficiency (CVID) is a heterogeneous disorder that is likely caused by a variety of molecular mechanisms that ultimately lead to a similar clinical phenotype. The European Society of Immunodeficiency (ESID) has proposed diagnostic criteria in an effort to standardize the diagnosis of CVID. These include (1) plasma IgG levels that are <2 standard deviations below the mean for age combined with a "marked decrease" in either IgM or IgA; (2) age of onset of immunodeficiency >2 years of age; (3) absent isohemagglutinins or poor responses to vaccines; and (4) defined causes of hypogammaglobulinemia have been excluded.

The peak age of onset of CVID is in the second or third decade of life and 50% to 60% of patients have a clinical phenotype consisting almost exclusively of increased bacterial sinopulmonary infections. With IgG supplementation, this group of

patients has a relatively benign course with long-term survival that is not unlike the normal population. The other half of patients have a complicated disease course with autoimmunity or lymphoproliferative disease that can involve the hematopoietic system, lungs, lymph nodes, liver, and bowel. The long-term outcome of this population is significantly worse, approaching only 40% survival over 40 years.[42]

Among the disorders seen in this population, a granulomatous, lymphoproliferative, interstitial lung disease (GLILD) affects approximately 30% to 40% of patients.[43] This often presents with decreasing lung function that is manifested by cough, decreased exercise tolerance, and sometimes hypoxemia. Typical findings on chest CT scan include diffuse nodules within the lung, opacities that have a "ground glass" appearance, bronchial wall thickening, and sometimes bronchiectasis. Lung biopsy generally demonstrates a lymphocytic interstitial pneumonitis with noncaseating granulomas and a follicular bronchiolitis with lymphoid aggregates of both B and T cells. This pattern is sometimes mistaken for sarcoidosis, although there are differences. Over time, this inflammatory process in the lungs will cause destruction of alveoli and contribute to development of bronchiectasis and emphysematous changes. If left unchecked, there is evidence that irreversible damage and fibrosis develop in many patients. High-dose corticosteroids are often used as first-line therapy to treat this process, and in many cases they are effective but do not typically lead to a lasting remission on their own. A recent study using a combination of anti-CD20 monoclonal antibody (rituximab) therapy and azathioprine in a small cohort of CVID patients with GLILD demonstrated dramatic responses with a prolonged remission of disease in many patients.[44]

In addition to pulmonary symptoms, GI complaints are common in CVID, affecting 20% to 30% of patients.[42] Patients who develop disease demonstrate a hypertrophic lymphoproliferation of Peyer's patches that causes a nodular lymphoid hyperplasia in the bowel. This is associated with abdominal discomfort, diarrhea, malabsorption, and weight loss and can cause significant morbidity. A variety of approaches have been taken to treat this process, but none have offered particularly dramatic results, although nonabsorbable steroid preparations have shown some benefit with minimal side effects. A more troubling complication observed in 5% to 10% of patients is a hepatitis that can cause severe hepatic dysfunction with development of hepatosplenomegaly and ascites.[42] Infectious causes are almost never identified, and liver biopsy demonstrates a nodular lymphoid hyperplasia in the liver parenchyma, not unlike that observed in the bowel. Liver disease is among the complications associated with a poor outcome.

Some 20% of subjects have additional clinical findings that are suggestive of autoimmunity/immune dysregulation including immune thrombocytopenia and hemolytic anemia, neuropathy, endocrinopathies, and skin disease. Skin involvement ranges from alopecia and vitiligo to psoriasis and granuloma annulare.[45,46]

In most cases of CVID, the molecular etiology of disease is unknown. There has, however, been some progress in identifying genetic defects associated with a CVID phenotype. The most common mutations identified are autosomal recessive defects in the transmembrane activator and calcium modulator and cyclophilin ligand interactor (TACI), which are found in 7% to 10% of patients with CVID.

Unfortunately, even in patients who have mutations that abrogate protein expression, the penetrance of disease seems to be highly variable with individuals from one family harboring the same mutation, having either a CVID phenotype, a selective IgA deficiency phenotype, or no disease. This inability to correlate disease phenotype or prognosis with the presence of a TACI mutation has raised the question of whether TACI genotyping offers clinical value. In addition to TACI, autosomal recessive mutations in the genes encoding the Baff receptor *(BAFFR)*, the inducible T-cell costimulator *(ICOS)*, *CD19*, *CD20*, *CD21*, *CD81*, and the LPS-responsive vesicle trafficking, beach and anchor containing protein *(LRBA)* have been identified in rare patients with features of CVID. These mutations have provided insight into basic immune mechanisms in humans but explain only a handful of all patients with CVID.[47,48] Lastly, hypomorphic mutations in *BTK* (X-linked agammaglobulinemia), *CD40L* (X-linked Hyper-IgM syndrome), *SAP*/*SH2D1A* (X-linked lymphoproliferative syndrome), and *RAG1*/*RAG2* can be associated with a CVID-like phenotype and, according to the diagnostic criteria for CVID, need to be excluded before making this diagnosis.[47]

B-cell numbers in peripheral blood are typically normal, but a subset of CVID patients has B-cell lymphopenia. In those patients with normal B-cell numbers, B-cell maturation, memory development, and immunoglobulin class-switching are often abnormal and can be assessed by detailed flow cytometry–based immunophenotyping of B cells. Varying classification schemes have been proposed to subtype patients according to their B-cell phenotype, and these subsets have been correlated with differences in risk for autoimmunity, etc.[49-51] B-cell immunophenotyping has therefore become a useful clinical tool in caring for patients with CVID. In addition to the humoral immune deficiency, many patients with CVID have impaired T-cell function with decreased CD4 or CD8 T-cell numbers, as well as abnormal T-cell proliferative responses in vitro to mitogens and antigens. Regulatory T-cell numbers and function have also been found to be decreased in patients with CVID.[52-56]

Selective Immunoglobulin A Deficiency

Selective IgA deficiency (SIgAD) is common in the general population with an incidence as high as 1 in 300 individuals in blood bank studies. The majority (>50%) of patients with selective IgA deficiency have no apparent symptoms that can be directly linked to their immune defect. Severe infections as a consequence of IgA deficiency alone are virtually unheard of. In the patients who do have symptoms, they are typically more suggestive of immune dysregulation and autoimmunity (eg, allergy, arthritis, diarrhea, celiac disease) than immune deficiency (sinusitis, otitis media, bronchitis, and pneumonia). In patients who are truly IgA deficient, sensitization to IgA itself can be a problem, leading to anaphylactic reactions during infusions of blood products including IVIg, red blood cells, platelets, etc. This is, however, quite uncommon and can often be managed by pretreatment with diphenhydramine, acetaminophen, and steroids before the start of the infusion.[57]

Specific Disorders: T Cells

22q11 Deletion Syndrome (DiGeorge Syndrome)

22q11.2 deletion syndrome or DiGeorge syndrome is among the few disorders that have isolated T-cell deficiency. Deletions within the 22q11.2 region of the long arm of chromosome 22 have been associated with various clinical syndromes including DiGeorge syndrome (DGS), velocardiofacial syndrome (VCFS), conotruncal anomaly face syndrome (CTFS), CATCH22 syndrome, and others. DiGeorge syndrome is the name most commonly associated with immune deficiency, so it is the focus of this discussion. While DGS is a complex syndrome that has been associated with a wide array of symptoms, the diagnostic criteria proposed by the European Society of Immune Deficiency (ESID) are relatively straightforward. These propose that a diagnosis of DGS should be strongly considered in patients who have <500 $CD3^+$ T cells/mm^3 and any two of the following three characteristics: (1) conotruncal cardiac defect (truncus arteriosus, tetralogy of Fallot, interrupted aortic arch, or aberrant right subclavian); (2) hypocalcemia requiring therapy for >3 weeks; and (3) deletion of chromosome 22q11.2. This chromosomal deletion syndrome occurs in approximately 1 in 4000 to 5000 births and causes haploinsufficiency of the genes encompassed in the deletion that can extend to include as much as 3 Mb of the chromosome.[58,59]

The characteristic T-cell lymphopenia of DiGeorge syndrome is thought to arise primarily from the absence of adequate thymic tissue and, at times, the diagnosis is suspected when the cardiac surgeon correcting a congenital heart defect finds little or no thymic tissue in the mediastinum. Most affected infants have low but not absent T cells, and absolute counts tend to improve over the first year of life. Both $CD4^+$ and $CD8^+$ T cells are low, yet $CD8^+$ T-cell numbers tend to be more affected in most patients. Despite low T-cell counts, most patients do not have significant problems with recurrent or severe viral or fungal infections. Some patients may have recurrent candidiasis. Bacterial infections of the upper respiratory tract including otitis media and sinusitis do occur but may be related more to anatomic issues associated with the facial anomalies than to the immunodeficiency per se. Rare patients have severe T-cell lymphopenia with essentially no T cells and are termed "complete" DiGeorge. These patients may have a clinical phenotype similar to SCID.[58,59]

Other prominent clinical features include hypocalcemia, which can be severe and persistent due to parathyroid hypoplasia; dysmorphic facial features that include small, low-set ears, hypertelorism, and micrognathia; renal anomalies including horseshoe kidney and a duplicated collecting system; and developmental delay including problems with speech acquisition, learning disabilities, and behavioral problems. Patients with DiGeorge syndrome have also been found to have an increased incidence of autoimmunity including cytopenias (particularly affecting red cells and platelets), juvenile idiopathic arthritis (JIA), and thyroiditis.

In symptomatic patients, the diagnosis of DiGeorge syndrome is typically made by confirming a deletion within the 22q11.2 region by fluorescence in situ hybridization (FISH) or quantitative polymerase chain reaction for deletion of the *TBX1* gene that lies within the deletion.[60] In approximately 10% of patients, deletion of this region cannot be detected despite presence of the classic clinical features.

Treatment of DiGeorge initially involves supportive care that may include cardiac support and calcium supplementation. In patients with severe T-cell lymphopenia or evidence of decreased T-cell function, prophylaxis against PJ pneumonia and IgG supplementation may be used. Blood for these patients should be irradiated to

prevent the risk of graft-versus-host disease. For those patients with the severe, "complete" form of the syndrome, grafting of allogeneic thymus slices into the thigh muscle has proven to be successful in recovering the T-cell lymphopenia, improving T-cell responses, and correcting the infectious susceptibility.[61,62] Hematopoietic stem cell transplant (HSCT) has been used in a handful of patients with mixed results.[63,64] In general, HSCT restores the T-cell counts and protects patients against further infection, but in the absence of a thymus, the T-cell graft is thought to consist primarily of long-lived, committed lymphoid progenitor T cells and not of cells derived from donor bone marrow stem cells. As a result, there is concern that the T-cell grafts may senesce over time, once again leaving the patient lymphopenic and susceptible to infection. There are currently no long-term therapies that can successfully correct the parathyroid defect.

Severe Combined Immune Deficiency

Made famous by "The Boy in the Plastic Bubble," a 1976 made-for-TV movie starring John Travolta, SCID is among the most severe immunodeficiencies. It is now known that this category of diseases is made up of a variety of related disorders caused by mutations in more than 20 different genes. The one thing that is common to all forms of SCID is deficiency of one or more subsets of T cells. In many cases, there are no circulating T cells. Depending on the genetic defect, patients may also lack B cells and/or NK cells. This has led to the useful convention of defining cases of SCID by their cellular phenotype (ie, $T^-B^+NK^+$, $T^-B^+NK^-$, $T^-B^-NK^+$, $T^-B^-NK^-$, etc.). The cellular phenotype suggests what the underlying genetic defect may be (see Table 103.3).[2] Because of the absence of functional T cells, patients with SCID typically come to medical attention because of severe or chronic viral infections, fungal infections, or autoimmunity. Physical examination findings in SCID that may provide some clues to the diagnosis include a paucity of palpable lymph nodes and absence of a thymic shadow on chest radiograph. In the overwhelming majority of SCID cases, this leads to death in infancy or early childhood if patients do not undergo curative treatment, such as HSCT or gene therapy. Unfortunately, the presence of infections makes HSCT or gene therapy much more complicated and substantially decreases the chances of survival. Because of this, efforts have been under way in the United States and other countries to perform screening of all newborns using dried blood spot cards obtained at birth to identify those who may have SCID. These efforts have led to the recognition that the incidence of SCID is approximately 1 in 40,000 live births in the United States.[65,66]

TABLE 103.3

Suggested Laboratory Tests for Basic Evaluation of Each Immune Compartment

	Complement	Phagocytes
INNATE	Numbers: Plasma levels of specific complement components (eg, C1 esterase inhibitor, C2, C3, C4) Function: CH50—functional test for classical pathway AH50—functional test for alternative pathway	Numbers: CBC with differential: Are neutrophil counts normal? Function: Expression of the CD11b/CD18 integrin on leukocytes Neutrophil oxidative burst test: dihydrorhodamine 123 or nitro-blue tetrazolium
	B Cells/Antibodies	**T Cells**
ADAPTIVE	Numbers:	Numbers:

	CBC with differential: Are lymphocyte counts normal? Lymphocyte subsets: Are T, B, and NK cell counts normal? Function: Vaccine titers: protein antigens (eg, tetanus or diphtheria titers) Vaccine titers: carbohydrate antigens (pneumococcal titers)	CBC with differential: Are lymphocyte counts normal? Lymphocyte subsets: Are T, B, and NK cell counts normal? Function: T-cell proliferation to mitogens/antigens Vaccine titers: protein antigens (eg, tetanus or diphtheria titers)

The laboratory evaluation for immunodeficiency should be individualized to each patient's clinical presentation.

CBC, complete blood cell count; *NK*, natural killer.

X-Linked Severe Combined Immunodeficiency

The X-linked form of SCID (X-SCID) is the most common type, accounting for ~40% of all SCID cases. It occurs as a result of mutations in the *IL2RG* gene, encoding the γ receptor chain (γc) used by a number of cytokine receptors including those for IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21. In the absence of a functional γc chain, cells are unable to respond to these cytokines. Because IL-2 and IL-7 are key growth factors for T cells, and IL-15 is the key growth factor for NK cells, patients with X-SCID lack T and NK cells but usually have normal numbers of B cells in their blood. The ability to make antibodies is nevertheless severely impaired due to the lack of T-cell help.

If not identified by newborn screening, infants with X-SCID typically present with severe infections. PJ pneumonia is common and often accompanied by severe viral infections with cytomegalovirus (CMV), EBV, respiratory syncytial virus (RSV), rotavirus, human metapneumovirus, and others. Adenovirus is particularly lethal in SCID, causing not only pneumonitis but also a severe, fulminant hepatitis. In countries where BCG is still used for vaccination, X-SCID patients may develop severe, systemic BCG-osis. Other symptoms that are frequently associated with X-SCID include diarrhea, failure to thrive, and candidiasis.

Flow cytometry testing to evaluate tyrosine phosphorylation of the STAT3 transcription factor in response to IL-21 stimulation can provide a rapid assessment of whether a patient may have an IL2RG or JAK3 defect (see later). Under normal circumstances, IL-21 stimulation of B cells causes rapid tyrosine phosphorylation in B cells that is absent in patients with IL2RG or JAK3 deficiency. The diagnosis is ultimately confirmed, however, by sequencing of the *IL2RG* gene.

HSCT has been the mainstay of therapy for X-SCID using a variety of pretransplant conditioning regimens. Some have strongly advocated the use of T-cell–depleted grafts from one of the haploidentical parents because they are readily available, but many patients transplanted using that approach have failed to obtain significant donor chimerism in the B-cell compartment, so they have remained dependent on IgG supplementation post transplant. X-SCID was also the first disorder successfully treated by gene therapy. Unfortunately, the retroviral gene therapy vector used to deliver the normal copy of the *IL2RG* gene had an unknown propensity to integrate within the T-cell oncogene *LMO2*, causing T-cell leukemias in a subset of treated patients.[67-69] Further studies are under way using alternative viral vectors with the hope that these may have a better safety profile.

JAK3-Deficient SCID

JAK3 is the tyrosine kinase immediately downstream of the common gamma chain

(γc). It transduces signals from cytokine receptors to the STAT5 transcription factor and to other intracellular signaling molecules. Approximately 30 different mutations have been identified that impair JAK3 function to varying degrees. Those that are severe have a $T^-B^+NK^-$ cellular phenotype similar to mutations in *IL2RG*. Approximately one-third of patients have milder mutations that allow some JAK3 function.[70,71] These patients can develop some T cells, although the T cells that develop are functionally abnormal. The clinical presentation is similar to that observed in γc-deficiency. Sequencing of the *JAK3* gene is required to confirm the diagnosis.

Interleukin-7 Receptor, CD3 Components, and CD45-Deficient SCID

Defects in the α-chain of the IL-7 receptor (IL7RA), CD3 subunits (γ, δ, ε), or CD45 can cause SCID with a $T^-B^+NK^+$ phenotype. As noted earlier, IL-7 is one of the two key growth and differentiation factors for T cells. As a result, mutations in the IL-7 receptor α-chain (CD127) lead to selective T-cell deficiency but allow normal development of B and NK cells.

Similarly, absence of any of the CD3 subunits specifically affects the ability of T cells to develop because CD3 makes up an essential part of the T-cell receptor complex. The T-cell receptor, including CD3 subunits, assembles in the endoplasmic reticulum and Golgi complex before trafficking to the cell surface. If any of the receptor subunits are absent (including any of the CD3 chains), the receptor is recycled and never makes it to the outer cell membrane. As a result, cells are unable to receive the TCR stimulation needed as they traffic through the thymus and they die by "neglect." Because the number of T cells entering the thymus is normal, the CD3 defects are unusual among SCID disorders in that the size of the thymus is normal. Of the three known CD3 defects (γ, δ, and ε), CD3γ deficiency may have a somewhat milder clinical phenotype that can present with moderate T-cell lymphopenia and recurrent pneumonia and otitis.

CD45 is a transmembrane tyrosine phosphatase present on most white blood cells. It regulates intracellular Src-family tyrosine kinases that are important for T-cell receptor function and activation. Autosomal recessive mutations of CD45 lead to T-cell deficiency and a SCID phenotype in affected infants.

DNA Recombination and Repair Defects in SCID

Rearrangement of the V, D, J, and constant regions of the T-cell receptor gene and B-cell immunoglobulin gene requires that double-stranded breaks be made in the DNA and that these breaks then be repaired after removal of intervening chromosomal fragments. The recombinase activating genes *RAG1* and *RAG2* are expressed in T and B cells and play an essential role in creating the necessary double-stranded DNA breaks in the TCR and immunoglobulin loci. A large complex of proteins including artemis (DCLRE1C), DNA-PKcs, cernunnos/XLF (XRCC4-like factor), and DNA ligase IV (LIG4) then play a role in repair of the DNA double-stranded breaks needed to create the final, recombined TCR or Ig locus. Because productive rearrangement of the TCR or Ig locus is a necessary developmental step during T- and B-cell maturation, complete failure in one of these processes results in lymphopenia, with few if any T or B cells in the blood, while generation of NK cells is generally unaffected. Because radiation induces double-strand breaks in DNA,

cells from patients with mutations in any of the proteins involved in DNA repair demonstrate decreased survival in vitro after radiation exposure (radiation sensitivity). This can be a valuable diagnostic clue in making a diagnosis.

Patients who have null mutations of any of these proteins have a clear $T^-B^-NK^+$ cell phenotype. There are, however, many mutations, particularly missense mutations or small in-frame deletions, that allow expression of a partially functional protein that can occasionally productively recombine a TCR or Ig gene locus. The cell in which this occurs is then able to pass the developmental block and proliferate in an attempt to fill the lymphopenic void that is otherwise present in SCID. These forms of SCID are termed “leaky” because they allow a small number of T (and occasionally B) cells to “leak” past the developmental block. Omenn syndrome, originally described in leaky RAG1 or RAG2 mutants, is a clinical phenotype that results from this leaky form of SCID. Affected infants typically develop a desquamative erythroderma after birth that is associated with the presence of oligoclonal, activated T cells in the skin, hepatosplenomegaly, lymphadenopathy, eosinophilia, and elevated IgE. Some develop autoimmune enteropathy and cytopenias. Affected patients are typically treated with T-cell–directed immunosuppression such as cyclosporine or FK506, followed by bone marrow transplantation. Leaky forms of SCID have now been described in a number of SCID-associated molecular defects including RAG1, RAG2, artemis, ligase IV, IL7RA, IL2RG, RMRP, and others.[72]

Adenosine Deaminase– and Purine Nucleotide Phosphorylase–Deficient SCID

Adenosine deaminase (ADA) deficiency was the first molecularly defined immunodeficiency with discovery of patients with SCID who lacked the enzymatic activity of ADA in the peripheral blood in the early 1970s. Adenosine deaminase (ADA) catalyzes the conversion of adenosine triphosphate (ATP), guanosine triphosphate (GTP), and their deoxy counterparts to adenosine diphosphate (ADP) and guanosine diphosphate (GDP). When enzyme activity is impaired or absent, intracellular levels of deoxy-ATP (dATP) rise to interfere with ribonucleotide reductase, such that DNA synthesis and repair are slowed and lymphocyte apoptosis is increased. Purine nucleotide phosphorylase (PNP) works further down this same metabolic pathway to convert deoxyinosine to hypoxanthine. Mutations interfering with this function cause deoxy-GTP accumulation and the inhibition of ribonucleotide reductase and DNA synthesis. In both cases, affected infants typically have a $T^-B^-NK^{-/low}$ cellular phenotype due to the toxic nature of the accumulated metabolites on lymphocyte development. Patients typically present with severe or recurrent viral infections or recurrent sinopulmonary infections in the first year of life.

Both syndromes are associated with other nonimmune symptoms, including skeletal abnormalities and osteochondrous dysplasia in ADA deficiency and neurologic deficits, developmental delay, and spasticity, in PNP deficiency. In both cases, the diagnosis can be made by detecting high levels of the toxic metabolites that build up in the peripheral blood in the absence of enzymatic activity. Sequencing of the *ADA1* or *PNP* genes can be done to confirm the diagnosis. ADA deficiency accounts for 20% or more of autosomal recessive SCID cases.

Aside from bone marrow transplantation, ADA-deficient infants can be treated with polyethylene glycol–conjugated ADA, which is injected intramuscularly once per week. Treatment efficacy is gauged by measuring plasma ADA activity and red cell dATP levels. Enzyme treatment has the advantage of speed of response coupled with safety.[73,74] The treatment is expensive, and many treated patients develop antibodies to the bovine protein, which may neutralize the effect of the enzyme. Hematopoietic stem cell transplant is effective in ADA deficiency but less so in PNP deficiency as it does not correct the neurologic deficits. Gene therapy for ADA deficiency has been quite successful, and unlike X-linked SCID and WAS, there have been no reported cases of leukemia despite the retroviral gene therapy vector backbone being similar.[75]

Zap-70–Deficient SCID

Zap-70 is a tyrosine kinase that is downstream of CD3 in the T-cell receptor signaling pathway. Absence of functional enzyme results in a characteristic SCID phenotype with decreased $CD4^+$ T cells but virtually absent $CD8^+$ T cells. Immunoglobulin levels are often decreased, and antibody responses to vaccination are typically absent because of the lack of effective T-cell help. The $CD4^+$ T cells that are present do not respond to antigen or mitogen stimulation, which uses the T-cell receptor, but they do proliferate and make cytokines in response to phorbol and ionomycin stimulation, which mimics TCR stimulation by activating kinases and calcium flux through downstream mechanisms. Bone marrow transplantation is effective in this disorder.

Defects in Antigen Presentation by MHCI or MHCII

The class II MHC complex generally presents peptide antigen derived from ingested material (either by phagocytosis or via the B-cell antigen receptor). Defects that interfere with the assembly or cell-surface expression of the class II MHC–peptide complex prevent effective antigen recognition by $CD4^+$ T cells, resulting in a SCID syndrome that presents in infancy with chronic diarrhea, failure to thrive, and occasionally autoimmune cytopenias. MHCII deficiency can result from defects in one of four DNA-binding proteins that regulate transcription of the MHC class II gene (*CIITA, RFXANK, RFX5,* and *RFXAP*). Founder mutations (particularly in *RFXANK*) that are common in the Mediterranean region have led to most affected patients having some familial ties to this geographic area. Because MHC class II presentation of antigen is abnormal, $CD4^+$ T cell counts are often low while CD8 counts are normal. A rapid preliminary diagnosis can be made by evaluating peripheral blood cells for expression of the class II complex by flow cytometry, which will detect reduced expression. Some patients can have a mild disease course and live well into adulthood with only supportive care, while others with the same mutation (even in the same family) may have a more severe phenotype. Bone marrow transplantation for MHC II deficiency has been challenging with survival rates typically approaching approximately 50%. In addition, there is a high rate of severe graft-versus-host disease (GvHD) in these patients, possibly because thymic epithelial cells that play a role in positive and negative T cell selection are not replaced by transplant and still do not express MHC II.[76]

The class I MHC complex presents peptide antigens derived from intracellular

proteins where proteolytically derived peptides are bound to the MHC I complex as it is generated and trafficked through the endoplasmic reticulum. Peptides that are generated in the cytosol are transported into the inner lumen of the endoplasmic reticulum by the peptide transporters TAP1 and TAP2. Mutations in either of these, or of tapsin to which they bind, have been identified. TAP mutations are typically associated with recurrent viral infections and recurrent sinusitis and bronchitis. The diagnosis is usually suspected when serologic typing for HLA class I antigens fails to give interpretable results, but molecular typing indicates intact MHC DNA. $CD8^+$ T-cell and NK cell counts are frequently (but not uniformly) decreased in these patients. Other cell subsets are typically normal. Heterogeneity in the phenotype may reflect differences in the underlying mutation and in the gene affected. Some patients may survive into the third decade. The role of HSCT in MHC I deficiency is unclear.

Immune Dysregulation, Polyendocrinopathy, Enteropathy, X-Linked (IPEX) is a syndrome of regulatory T-cell deficiency. Natural regulatory T cells comprise a subset of $CD4^+$ T cells that regulate immune responses and play a critical role in peripheral immune tolerance. IPEX is caused by mutations in the *FOXP3* gene located on the X chromosome, which encodes a key transcription factor that is required for the generation of functional regulatory T cells (Treg). In the absence of FOXP3, patients present with severe, early-onset, systemic autoimmunity that is the result of having decreased Treg cell function. Almost all patients with IPEX present with enteropathy within the first 6 months of life. The enteropathy is typically characterized by profuse, watery diarrhea (often nonbloody) and villus atrophy. The majority of patients have an eczematous dermatitis that typically begins in the first months of life. More than half (60%-70%) of patients also develop an early-onset endocrinopathy that is almost exclusively either thyroiditis or type I diabetes. The most consistent laboratory abnormality among patients is a significantly elevated serum IgE level. In addition to these characteristic clinical and laboratory features, patients also have a high incidence of other severe autoimmune disorders, including hemolytic anemia, thrombocytopenia, neutropenia, hepatitis, and renal disease.

Recognition of the clinical features of IPEX is the first step in diagnosing this disorder. Sequencing of the *FOXP3* gene remains the gold standard for making a diagnosis of IPEX, although sequencing needs to encompass noncoding areas of the gene including the upstream noncoding exon and the polyadenylation signal sequence in order to cover all regions in which pathogenic mutations have been identified.[77,78] Flow cytometry to measure FOXP3 protein expression and $FOXP3^+$ regulatory T cells (Treg) is a helpful adjunct to gene sequencing, although only ~25% of patients have mutations that are predicted to completely abrogate FOXP3 protein expression. The remainder of patients have varying degrees of $FOXP3^+$ Treg deficiency due to the fact that mutant FOXP3 may not support normal Treg development. As a result, flow cytometry by itself is not considered to be a sufficiently reliable screening test for IPEX.

Initial therapy for IPEX typically consists of aggressive supportive care (eg, parenteral nutrition, insulin, thyroid hormone) combined with T-cell–directed immune suppression using agents such as tacrolimus, cyclosporine, or rapamycin. Hematopoietic stem cell transplantation (HSCT) is currently the only curative therapy for IPEX. Early HSCT using a nonmyeloablative conditioning regimen before the onset of autoimmune-mediated organ damage usually leads to the best

outcome and limits the adverse effects of therapy.[79,80] Because Tregs constitutively express the high-affinity IL-2 receptor, they have a selective growth advantage in vivo. As a result, complete donor engraftment in all hematopoietic lineages may not be necessary because preferential engraftment of donor Treg cells can be sufficient to control the disease.[81]

Specific Disorders: Other Complex or Combined Immunodeficiencies

Wiskott-Aldrich Syndrome

Wiskott-Aldrich Syndrome (WAS) is unique among immunodeficiency disorders because affected patients have both an infectious susceptibility and a bleeding disorder. The bleeding problems are caused by the platelets being small (mean platelet volume <5 fL), dysfunctional, and decreased in number (usually platelet counts <70,000/μL). Patients with WAS typically present in infancy with bloody diarrhea and/or bruising, recurrent upper respiratory tract infections, and eczema. The incidence of hematopoietic malignancies is high. IgE levels are often elevated. Serum IgG levels and T-cell counts are often normal in infancy but may decrease over time. Responses to vaccination, particularly with carbohydrate antigens such as Pneumovax, are often abnormal.

WAS is caused by mutations in the *WAS* gene, located on the short arm of the X chromosome. Inheritance is X-linked recessive. There is a distinct genotype/phenotype correlation of mutations in WAS: Mutations that destroy WAS protein (WASp) expression lead to the full syndrome of immunodeficiency and platelet dysfunction. Mutations that allow expression of a mutant WASp protein are typically associated with a milder X-linked thrombocytopenia (XLT) phenotype in which the platelet dysfunction persists but the immunodeficiency is mild. Point mutations in the CDC42 binding domain of the WASp protein lead to a third phenotype of X-linked neutropenia (XLN) that is generally not accompanied by bleeding abnormalities.[82,83]

The WASp protein is expressed primarily in lymphoid and myeloid cells, where it functions to nucleate actin polymerization in the cell. Patients with WAS therefore have problems with directed migration of neutrophils and with clustering and signaling through T-cell and B-cell antigen receptors (this causes decreased signaling into the cell and abnormal proliferative responses). A diagnosis of WAS can be confirmed by demonstrating the absence of WASp protein in cells by flow cytometry or Western blotting or by identifying a mutation in the *WAS* gene.

Treatment of WAS initially involves supportive care including treatment of any acute infections and management of any bleeding episodes. In general, repeated platelet transfusions are avoided because of the concern that patients will become sensitized to a wide array of HLA types, which may increase the risk of complications during subsequent hematopoietic stem cell transplant (HSCT). Splenectomy can increase platelet counts, but it also increases the risk that patients may die of sepsis with encapsulated organisms, so there continues to be significant controversy surrounding the role of splenectomy in WAS. Patients with the full WAS phenotype should be evaluated for HSCT with matched related or unrelated donor bone marrow or cord blood.[84] Haploidentical transplants have proven risky in

this disease and are generally avoided. The role of HSCT in XLT remains controversial.[85] Some have advocated that the benefits for curing the bleeding problems are worth the risk if a matched sibling donor is available. Gene therapy has been successful in a small number of patients with WAS, but like the X-SCID gene therapy trials, some treated patients developed T-cell leukemias as a result of integration of the viral gene therapy vector near an oncogene.[86]

Cartilage-Hair Hypoplasia

Cartilage-hair hypoplasia (CHH) is a complex disorder characterized by skeletal dysplasia with short limbs (metaphyseal chondrodysplasia), sparse hypoplastic hair, gastrointestinal problems, and a variable immunodeficiency. CHH is caused by mutations in the *RMRP* gene, which encodes the 267 base-pair RNA component of the RNase MRP complex, which plays a role in processing of precursor ribosomal RNA. The mechanism by which autosomal recessive mutations in *RMRP* cause the clinical features of CHH is unknown. The largest populations of CHH patients have been identified among the Old Order Amish and Finnish populations. Virtually all patients with CHH have some degree of immunodeficiency that can range from a mild humoral defect with decreased vaccine responses to a SCID-like phenotype associated with progressive lymphopenia and severe infections with bacteria, viruses, and fungi. A leaky-SCID phenotype has also been described in RMRP deficiency. The diagnosis of CHH can be made on the basis of the clinical phenotype and confirmed by sequencing of the *RMRP* gene. Immunologic features of CHH can be corrected by hematopoietic stem cell transplantation, but the other features persist.[87]

Radiation Sensitive Disorders: Ataxia Telangiectasia and Nijmegen Breakage Syndrome

Ataxia telangiectasia (AT) is a disorder associated with progressive neurologic decline, immunodeficiency, and propensity to malignancy. It is caused by autosomal recessive mutations in the *ATM* gene, which encodes a serine/threonine kinase that acts together with the NBS1 protein as one of the major sensors of double-stranded DNA breaks in the cell. ATM phosphorylates key proteins involved in activation of the DNA damage repair checkpoint, leads to cell-cycle arrest, and then leads to double-stranded DNA break repair. In the absence of functional ATM or NBS1, cells have a marked sensitivity to ionizing radiation. Because rearrangement of the TCR gene and the immunoglobulin gene loci also require double-stranded DNA break repair, these processes may be affected as well.

Patients with ataxia telangiectasia usually present in early childhood (most commonly between 2 and 5 years of age) with cerebellar ataxia that progresses to unsteady gait and, over time, choreoathetosis. Telangiectasias (small tufts of dilated blood vessels under the surface of the skin or mucous membranes) typically develop first on the conjunctivae and are later seen on the nose, ears, and shoulders. They can be an important diagnostic clue in a child with progressive ataxia. The majority of patients have immunoglobulin deficiency of varying degrees and can develop

sinopulmonary symptoms and sepsis. Progressive neurodegeneration can compromise coughing, so it is hard to determine whether respiratory infections occur more as a result of the immunodeficiency or the motor defects. Most affected individuals have elevated serum α-fetoprotein levels, which can be useful diagnostically. Malignancies are an important complication as a result of the DNA-repair defect. Acute T-cell leukemias are common and often demonstrate chromosomal translocations that affect the chromosomal regions involved in T-cell receptor gene rearrangements. B-cell lymphomas also occur and are usually associated with 11q22-23 chromosomal deletions. There is also an increase in the frequency of epithelial tumors in both homozygotes and ATM mutation carriers. Affected patients usually die in the second or third decade of life.

Other DNA repair defects that cause varying degrees of ataxia and/or mild mental retardation include an ataxia-like syndrome caused by mutations in *MRE11* and the Nijmegen breakage syndrome (NBS), caused by mutations in *NBS1*. In addition to an immunodeficiency like that observed in AT, patients with NBS have marked microcephaly, mild developmental delay/mental retardation, and a strong propensity to develop lymphomas. Another DNA repair defect, Bloom syndrome, caused by mutations in a DNA helicase (RecQ proteinlike-3), results in excess sister chromatid exchanges; it is associated principally with lymphomas and cancer. Multiple primary tumors occurring at an early age are common. Reduced growth in childhood results in a proportional dwarfism that, with cutaneous telangiectasia, is a useful physical sign. Inheritance is autosomal recessive, and the disease occurs with increased frequency in Ashkenazi Jewish populations. Chronic lung disease occurs and may be related to low levels of IgA and IgM.[88]

Mammalian Susceptibility to Mycobacterial Disease

Under normal circumstances, intracellular pathogens like mycobacteria induce production of IL-12 and IL-23, which play a role in driving maturation of naïve T cells into activated T helper type I (Th1) cells that produce interferon-γ (IFN-γ). IFN-γ then acts on a variety of cells including phagocytes (neutrophils, monocytes, and dendritic cells) to induce a number of interferon-inducible genes. Multiple molecules in this signaling pathway have been found to be defective in patients with intact cellular immunity who have invasive, nontuberculous mycobacterial infections. Mutations in the genes encoding the IL12 p40 subunit *(IL12B),* the IL-12 receptor β1 chain *(IL12RB1),* the *TYK2* tyrosine kinase that is associated with the IL-12 receptor and required for phosphorylation of the STAT4 transcription factor *(TYK2),* the IFN-γ receptor subunits (*IFNGR1* and *IFNGR2*), and the STAT1 transcription factor that is activated in response to IFN-γ *(STAT1)*. Mutations in this pathway are also associated with other infections including invasive salmonellosis and severe viral infections *(STAT1).* In addition to these genetic defects, patients with invasive mycobacterial disease have now been identified with neutralizing autoantibodies to IFN-γ. Together, these discoveries demonstrate a major role for the IL-12/IL-23/IFN-γ axis in normal human immunity.[89] For patients with the milder, autosomal-dominant IFN-γ receptor defects, IL-12 p40 defects, IL-12 receptor defects, and TYK2 defects, antimicrobial therapy and IFN-γ treatment are often sufficient to treat invasive mycobacterial infections and prevent future infections. For patients with the more severe, autosomal recessive IFN-γ receptor defects, IFN-γ supplementation provides no benefit and hematopoietic stem cell transplantation is warranted.[90,91]

Susceptibility to Hemophagocytic Lymphohistiocytosis and Severe EBV Infection

Several defects affecting intracellular trafficking of vesicles and granules are associated with susceptibility to hemophagocytic lymphohistiocytosis (HLH). This group includes some phenotypes that are quite distinctive, including Chédiak-Higashi (CHS) and Griscelli (GS) syndromes, which are both associated with a partial oculocutaneous albinism. Patients with CHS have pyogenic infections and periodontitis: Their neutrophils have reduced chemotaxis and contain giant inclusion bodies (lysosomes). Patients with GS also have neurologic defects ranging from developmental delay to fatal neurodegeneration. Their neutrophils are dysfunctional, but they lack the giant granules of CHS. In vitro tests show low natural killer cell and cytotoxic cell function. CHS, GS, and X-linked lymphoproliferative syndrome (XLP) share susceptibility for HLH—an accelerated inflammatory process that, in the case of XLP, may be triggered by EBV. The genes responsible for these syndromes are *LYST, RAB27A, SH2D1A,* and *XIAP/BIRC4,* respectively, whereas genes for a further group of proteins (Perforin, Munc 13-D, and Syntaxin 11) are associated with familial hemophagocytic lymphohistiocytosis.[92]

Toll-Like Receptors and Innate Signaling Pathway Defects

Toll-like receptors are a family of at least 10 pattern recognition receptors that are expressed in varying combinations on a broad array of immune and nonimmune cells. They recognize particular types (patterns) of molecules derived from pathogens (eg, bacterial lipopolysaccharide, flagellin, mannan, CpG dinucleotides, viral dsDNA). Triggering of Toll-like receptors activates intracellular signaling pathways, many of which converge on a common pathway using the IRAK proteins and MyD88, which in turn activate the IκB kinase complex (NEMO/IκKα/IκKβ), ultimately leading to phosphorylation and degradation of IκBα and activation of the NF-κB transcription factor complex.

Mutations in TLR signaling pathways have now been associated with major infectious susceptibilities: Mutations in *IRAK4* and *MyD88* have been identified in patients with susceptibility to invasive pyogenic bacterial infections, including particularly *Streptococcus pneumoniae, Staphylococcus aureus,* and *Pseudomonas aeruginosa*. Interestingly, patients with IRAK4 or MyD88 deficiency tend to have problems with invasive pyogenic bacterial infections in childhood, but these subside over time, presumably as a result of the adaptive immune response covering for this innate defect. Mutations in *TLR3, TRIF, TRAF3,* and *UNC-93B* have been identified in patients with susceptibility to herpesvirus encephalitis. Defects in NEMO and IκBα also cause susceptibility to infections with pyogenic bacteria and mycobacteria and are associated with an anhydrotic ectodermal dysplasia phenotype. The severity of immunodeficiency and ectodermal dysplasia is quite variable and depends on the specific mutation that is present.[93]

Chronic Mucocutaneous Candidiasis Syndromes

Chronic mucocutaneous candidiasis (CMC) is a clinical syndrome associated with chronic and recurrent *Candida* infections of mucosae, particularly oral and vaginal, together with nail-bed infections but generally without systemic infection. CMC can occur in isolation or as part of a broader clinical syndrome such as in APECED

(autoimmune poly endocrinopathy, candidiasis, ectodermal dystrophy). Recent discoveries have determined that in almost all cases, CMC is associated with abnormalities in development of Th17 effector T cells or with the production of, or responses to, the cytokine IL-17. These include autosomal recessive mutations in IL-17F or the IL-17 receptor α-subunit, dominant loss-of-function mutations in STAT3, and dominant gain-of-function mutations in STAT1.[94]

Recently, the CMC associated with APECED was found to be the result of autoantibodies to IL-17 and IL-22.[95,96] APECED is caused by mutations in AIRE1, a nuclear protein that regulates the expression of self-antigens by thymic medullary epithelial cells, where it plays a role in T-cell selection and maturation. Other features of this disorder include endocrinopathies (hypoparathyroidism, adrenal insufficiency, and diabetes), alopecia areata, nail dystrophy, and vitiligo.

Autoimmune Lymphoproliferative Syndrome

The clinical phenotype of autoimmune lymphoproliferative syndrome (ALPS) is characterized by massive lymphadenopathy and hepatosplenomegaly in most cases. In addition, patients have problems with recurrent episodes of autoimmune hemolytic anemia and thrombocytopenia. The defects that have been identified in patients with this group of disorders are all associated with abnormalities in lymphocyte apoptosis. These include *FAS* (CD95), Fas ligand *(FASL), FADD,* Caspase 10 *(CASP10), NRAS,* and *KRAS*. Peripheral blood T- and B-cell counts are generally normal, but in almost all cases, there is an increased percentage of $\alpha\beta$-TCR$^+$ double-negative T cells that lack expression of both CD4 and CD8. A predisposition to developing lymphoid malignancies has been described in ALPS but is thought to be primarily in those patients who have mutations in the death domain of FAS. In addition to elevated double-negative T cells, patients with ALPS frequently have elevated levels of IL-10 and vitamin B_{12} in the blood, which can be valuable diagnostically in patients with suspected ALPS. Patients with mutations in caspase 8 *(CASP8)* were previously classified as ALPS but are now considered to be a unique syndrome that may have lymphadenopathy and splenomegaly, but recurrent respiratory tract infections and mucocutaneous herpesvirus infections are prominent, both unusual features in ALPS.[97,98]

A variety of immunosuppressive therapies have been tried in ALPS to control the recurrent autoimmune cytopenias and severe hepatosplenomegaly. Most of these were only modestly successful, as was splenectomy. Recent studies have, however, demonstrated a dramatic response to rapamycin therapy in many patients with ALPS, often causing shrinkage of the lymph nodes and spleen back to their normal size.[99,100]

Laboratory Evaluation of the Immune System

A basic laboratory workup to screen for significant defects in each of the four major compartments of the immune system can be done by most practitioners before making a referral to a clinical immunologist for further, detailed evaluation. In simple terms, this workup should include evaluation of numbers and function for each of the four immune system compartments. A recommended workup using this approach is outlined in Fig. 103.3.

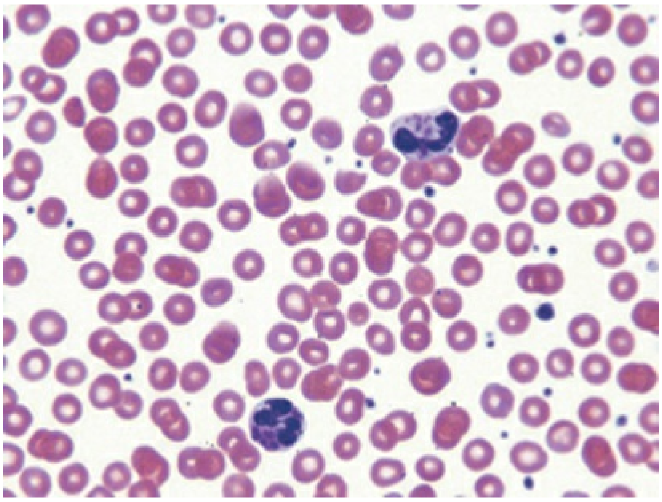

FIG. 103.3 Peripheral smear showing mature and band neutrophils *(top)* with basophilic cytoplasmic inclusion consistent with Chediak-Higashi syndrome.

Diagnostic Testing—Complement

Screening for complement deficiency should be performed in patients with recurrent episodes of bacteremia, meningitis, or disseminated gonorrhea. Since more than 30% of patients with recurrent *Neisseria* infections have complement deficiency, it is imperative that prompt testing of the complement system be done in these individuals. The screening test of choice for complement deficiencies is the CH50 test, which measures functional complement activity in the plasma. The CH50 will only identify defects in the classical pathway, which is typically sufficient because alternative pathway defects are exceedingly rare. If an alternative pathway defect is suspected, however, an analogous test (the AH50) can be performed. In order for the CH50 to give accurate results, the blood specimen needs to be handled carefully because complement is very heat labile. In general, it is recommended that any abnormal CH50 test should be repeated to confirm a complement deficiency. The CH50 is typically very low or absent in patients with a complement component deficiency. A CH50 result that is only moderately low is often seen in situations where the specimen was handled incorrectly or in patients with autoimmune disease such as lupus or mixed connective tissue disease. Once an abnormal CH50 test is confirmed, specialized testing to identify the specific complement component that is absent can be performed.

Diagnostic Testing—Phagocytes

Assessment of patients for a possible phagocytic disorder requires that both the number and the function of phagocytes be evaluated. Numbers are easily evaluated using a complete blood count with differential. If there is a concern for cyclic neutropenia, neutrophil counts may need to be evaluated three times weekly for 3 to 4 weeks to identify the nadir.[101] Functional testing includes evaluation of CD11/CD18 integrin expression on myeloid cells by flow cytometry if the patient has symptoms suggestive of leukocyte adhesion deficiency (LAD). In cases of suspected chronic granulomatous disease (CGD), evaluation of neutrophil oxidative burst function is

essential. Traditionally this was done using nitrobluetetrazoleum (NBT) but is now performed using dihydrorhodamine (DHR), a reagent that permeates neutrophils and fluoresces when reduced by a normal neutrophil oxidative burst. Fluorescence is measured by flow cytometry. The DHR test is sensitive enough to differentiate most cases of X-linked CGD from autosomal recessive CGD, making it a particularly useful clinical assay.[102,103]

Diagnostic Testing—B Cells and Antibodies

The diagnosis of antibody deficiency needs to evaluate both the quantity and the quality of the antibody response. Quantity is easily evaluated by measuring quantitative immunoglobulin levels (IgG, IgM, IgA, and IgE) in the blood and comparing these with the age-appropriate normal ranges. Evaluating the quality of the antibody response can be done by measuring specific antibody titers to vaccines that the patient has received. Generally, responses to both protein antigens (eg, tetanus, diphtheria, hepatitis B) and carbohydrate antigens (23-valent unconjugated Pneumovax) need to be assessed to confirm normal antibody responses. Patients who respond appropriately to protein antigens but do not respond to carbohydrate antigens may have *specific antibody deficiency* and may require additional workup. Recent guidelines regarding the interpretation and use of diagnostic vaccination have recently been published.[104]

In addition to evaluating antibody quantity and quality, it is essential to determine whether patients have normal B-cell numbers by evaluating lymphocyte subsets. The use of more detailed B-cell immunophenotyping to evaluate B-cell development, the presence of $CD27^+$ memory B cells, and the ability of memory B cells to undergo immunoglobulin class switching has become standard of care in many clinics as it provides valuable diagnostic and prognostic information.[105]

Flow cytometry testing to assess the expression of specific proteins that are defective in B-cell and antibody deficiency disorders including BTK, CD40 ligand, CD40, ICOS, CD27, BAFF receptor, etc. can be performed in specialty laboratories and offer the ability to rapidly obtain a molecular diagnosis. This is typically supplemented by sequencing of specific genes.

Diagnostic Testing—T Cells

T-cell testing begins with determination if the absolute lymphocyte count is normal, as well as assessment of lymphocyte subsets ($CD4^+$, $CD8^+$, NK, Treg). Gross T-cell function can be ascertained beginning with T-cell proliferation assays. Vaccine titers for tetanus or diphtheria can also be quantified. Diagnosis of specific T-cell defects are usually made with flow cytometry to demonstrate alteration or absence of some lymphocyte protein or focused genetic testing.

Treatment of Immune System Disorders

Treatment: Complement

Patients with complement deficiency are susceptible to fulminant sepsis and other deep-seated infections caused by encapsulated organisms. For this reason, patients

should be given a letter, laminated card, medical alert bracelet/necklace, or Health Data "Me" app that they can keep with them at all times with contact information for their primary care physician and clinical immunologist and a message indicating that they have a complement deficiency. The message should emphasize that there should be no delay in giving parenteral antibiotics should they be ill. For patients who live at a distance from skilled medical care, consideration should be given to providing a dose of parenteral antibiotic such ceftriaxone that can be administered by the patient or a family member when they become ill, before a lengthy trip to the hospital. The efficacy of chronic prophylactic antibiotics to prevent infection in patients with complement deficiency is not well studied and remains a significant question in this group of disorders. In addition to preparing for and treating infections, patients should also be regularly screened for autoimmunity by history, physical examination (ie, blood pressure monitoring), and laboratory testing including BUN, creatinine, and urinalysis to monitor for signs of glomerulonephritis because this is a common autoimmune manifestation.

Treatment: Phagocytes

As noted earlier, management of phagocytic disorders revolves around having a heightened suspicion for infections, aggressively treating acute infections using antibiotics and G-CSF as needed, and developing a prophylaxis regimen that is both effective and reasonable from a patient standpoint. At times, patients continue to have recurrent or severe infections despite these efforts and require more definitive therapy. As indicated earlier, hematopoietic stem cell transplantation (HSCT) has been shown to be effective in many, but not all, phagocytic disorders. Gene therapy has been attempted for both X-linked CGD[106] and for LAD-I,[107] but neither has been particularly successful thus far and at this point is considered to be experimental. Ongoing research to address the challenges of gene therapy that are unique to these two disorders is under way.

Treatment: B Cells and Antibodies

Immunoglobulin Replacement

In patients with antibody-deficiency, replacement of IgG is critical to maintaining health and preventing long-term complications associated with recurrent infections. Immunoglobulin replacement therapy has been found to be effective when administered intravenously (IVIg), subcutaneously (SCIg), and intramuscularly (IMIg). FDA-approved products support administration via any of these routes. With that said, because of significant discomfort associated with IMIg administration, this route is rarely used in the United States. Most patients are maintained on either IVIg or SCIg depending on patient preference and provider recommendations related to each patient's clinical need. Because the half-life of IgG in the circulation is ~21 days under normal circumstances, IVIg is typically administered every 3 to 4 weeks providing high peak levels followed by a decline over the ensuing weeks to a trough before the next infusion. In contrast, SCIg is typically administered 1 to 2 times per week in smaller doses providing a more "steady-state" level of IgG in the circulation. IgG products are prepared from the pooled plasma collected from thousands of healthy donors and therefore contain a

broad range of antibodies. A reasonable starting dose of either IVIg or SCIg is 400 to 500 mg/kg/month. This can be divided into the number of doses required to administer the necessary monthly volume (IgG preparations range in concentration from 5 gm/100 mL [5%] to 20 gm/100 mL [20%]). In most patients, a trough IgG level of 600 mg/dL in the blood is a reasonable initial target but the dose can then be increased or decreased to achieve a trough IgG level that prevents both acute infections and development of progressive lung disease. There is evidence that at least for bacterial pneumonia, higher IgG trough levels are directly correlated with a decreased risk of infection.[108] Supplemental IgG is generally effective at preventing lower respiratory tract infections (bronchitis and pneumonia), but the response of upper tract disease (particularly sinusitis) is more variable. Some patients have persistent sinus symptoms that can be a significant clinical problem despite IgG therapy. In these patients, the addition of prophylactic antibiotic therapy or increasing the frequency or dose of IgG infusions may be beneficial.

Side effects with IVIg therapy are relatively common, occurring in up to 25% of treated patients.[109] Side effects include headaches, nausea, vomiting, chills, fatigue, fever, rash, and aseptic meningitis. These can often be managed by changing the IgG product being used, pretreating with diphenhydramine, acetaminophen, and corticosteroids steroids before infusion, or slowing the rate of infusion. Patients who have persistent symptoms despite these measures can often tolerate subcutaneous IgG supplementation (SCIg).

Prophylactic Antibiotics

It has been increasingly recognized that in many patients with antibody deficiency, replacement of IgG (even to normal levels) may not prevent all clinically significant infections. The addition of prophylactic antibiotics has been used as an adjunct to IgG therapy to try and improve control of infections and decrease morbidity. Unfortunately, to date, there have been no well-performed studies that argue strongly either for or against the use of prophylactic antibiotics to improve outcomes. Similarly, there have been virtually no studies that support a particular antibiotic regimen as being superior for prophylaxis. Because many patients with antibody deficiency have evidence of bronchiectasis and chronic lung disease, some providers, extrapolating from the lung transplant and cystic fibrosis literature, have used thrice-weekly macrolide antibiotics as a prophylactic regimen in an attempt to prevent progression of lung pathology. Further studies are needed to clarify the role of prophylactic antibiotics and to define the optimal regimen.

Treatment: T Cells

SCID was uniformly lethal in the first years of life until Good et al. successfully reconstituted an affected infant with a transplant of sibling bone marrow. Experience in subsequent years has shown that patients with B-cell–positive SCID (IL2RG, JAK3, IL7RA, etc.) readily reconstitute their T-cell deficiency but may not develop significant B-cell chimerism. The reasons for this are not entirely understood, but various hypotheses have been put forward. From a practical standpoint, a lack of donor B-cell engraftment may lead to a chronic need for IgG replacement therapy even after transplant because patients may not be able to mount sufficient antibody responses. Patients with B-cell–negative SCID are more likely to have successful

donor engraftment of both T- and B-cell lineages and more likely to recover full humoral immune function.

One of the most significant challenges in the treatment of SCID is that in the absence of family history, most patients come to attention because of infections. These are most commonly PJ pneumonia and severe viral infections (see earlier). PJ pneumonia can be treated but may lead to lung damage, whereas viral infections may or may not be controllable. In addition, many SCID infants have significant diarrhea and weight loss by the time they reach a transplant center. Together, these complications increase the risk of adverse outcomes during transplantation for SCID and have been the major impetus for adding SCID to state newborn screening panels. Initial management before transplant involves aggressive supportive care, antimicrobials to treat any intercurrent infections (bacterial, viral, and fungal), antimicrobial prophylaxis to prevent future infections, and IgG replacement therapy.

There is significant debate about the best pretransplant conditioning regimen for patients with SCID to balance safety and efficacy. In general, those patients that have a matched sibling donor receive no conditioning before receiving unmanipulated bone marrow. For other patients, a variety of conditioning regimens ranging from no conditioning to fully myeloablative regimens have been tried. Similarly, a range of manipulated and unmanipulated stem cell sources have been tried including matched bone marrow, matched peripheral blood, cord blood, and haploidentical. Lastly, a variety of prophylactic immunosuppressive regimens have been used in the early posttransplant period to limit GvHD and prevent graft rejection. Each option has advantages and disadvantages, which has led to the spectrum of transplant regimens that have been attempted for SCID. Current efforts are under way to assess which regimens offer the best outcomes and lowest risk.[110-113]

CHAPTER 104

Acquired Immune Dysfunction

Gwenn E. McLaughlin, Brent J. Pfeiffer

PEARLS

- Most patients admitted to the pediatric ICU are immunosuppressed to varying degrees.
- Critical illness induces immunoparalysis, a phenomenon marked by downregulation of major histocompatibility complex class II molecule expression on the surface of monocytes, but not B cells. Suppressed monocyte/macrophage function reduces clearance of immune complexes, impairs antigen-presenting capabilities, and decreases natural killer cell function.
- Worldwide, protein calorie malnutrition is the most common cause of acquired immunodeficiency. Exposure to immunomodulatory medications increasingly accounts for cases of secondary immunodeficiency.
- The long-term effects of transfusions on the immune system and subsequent disease susceptibility are unknown, but even 19 years after a blood transfusion, recipients have fewer peripheral T cells, particularly helper T cells, than nonrecipients.
- Children with chronic immunosuppression are at risk for reactivation of latent viruses such as cytomegalovirus, Epstein-Barr virus, and adenovirus, as well as tuberculosis.
- Pneumocystosis is still the most common AIDS-defining illness in children and can present with variable pulmonary infiltrates, but hypoxemia is often out of proportion to clinical and radiographic examination.
- Lymphomas in immunodeficiencies are generally of B-cell type and often arise in the CNS.
- Postexposure prophylaxis for occupational HIV exposure should begin as soon as possible and continue for 4 weeks.

Acquired immune dysfunction is by definition a secondary phenomenon following another disease process, such as infection or trauma, or an intended or unintended

effect of therapy. Protein calorie malnutrition probably accounts for the greatest number of immunodeficient patients in ICUs worldwide, whereas HIV infection is the most widely recognized cause of acquired immune deficiency. Impairments in humoral and cellular immunity occur as a consequence of immaturity, malignancy, transfusion, sepsis, shock, viral infections, tuberculosis (TB), and malaria.[1] Iatrogenic immunosuppression occurs most frequently with medications given to either inactivate or kill lymphocyte populations, particularly those used in cancer chemotherapy and autoimmune disease, and to control transplant rejection. When all these precipitants of immunodeficiency are taken into account, it becomes apparent that most patients admitted to the pediatric ICU (PICU) are immunosuppressed, although to varying degrees. Patients with acquired immunodeficiency are at risk for opportunistic infections and unusual presentations of common infections. If immunosuppression is known or suspected, the physical examination should focus on the mucosal surfaces, catheter entry sites, skin (including wounds), and CNS. Understanding patterns of disease that are specific to each type of immune dysfunction can lead to both earlier appropriate empiric therapy and diagnostic tests. Unlike congenital immunodeficiency, many cases of acquired immunodeficiency are reversible with treatment or resolution of the primary illness or injury.

Immune Function and Critical Illness

Critical illness often involves the activation of innate and adaptive immunity responses that must be regulated for the patient to survive (see also Chapters 101 and 102).[1] The body responds to stress by releasing proinflammatory cytokines such as tumor necrosis factor–alpha (TNF-α), interferon-gamma (INF-γ), and interleukins (IL-1, IL-2, IL-6, IL-8, and IL-12) from various immune cell types.[1] Tissue injury, epithelial barrier disruption, and cell destruction potentiate the proinflammatory response through the Toll-like receptors (TLRs) and other pattern-recognition molecules involved in innate immunity.[2] To regulate the proinflammatory reaction, antiinflammatory agents such as IL-10, IL-4, IL-6, transforming growth factor β (TGF-β), soluble TNF receptor, and endogenous corticosteroids suppress immune function.[3-6] Prolonged recovery of the immune system after critical illness is known as immunoparalysis and puts the patient at increased risk of developing nosocomial infections.[7-10]

In 1986, a group of trauma surgeons recognized an association between late mortality after severe trauma due to secondary infections and suppressed monocyte function, specifically antigen presentation.[4] Several subsequent studies demonstrated downregulation of major histocompatibility complex (MHC) class II (human leukocyte antigen [HLA]-DR) molecules on the surface of monocytes after severe trauma, cardiopulmonary bypass, neurosurgical procedures, acute pancreatitis, and severe sepsis.[4,7-14] Suppressed monocyte/macrophage HLA-DR expression reduces immune complex clearance and impairs the antigen-presenting capabilities of the innate immune system, thus limiting activated T-cell interactions with monocyte/macrophages expressing HLA-DR-antigen complexes. Helper T-cell interaction with monocytes/macrophages is necessary to activate pathogen-killing mechanisms, produce chemokines, and promote leukocyte mobility. The interaction is also interferon gamma (INF-γ) dependent.[15] Immunoparalysis is confirmed in the

laboratory by reduced expression of HLA-DR antigens on peripheral blood monocytes and decreased ex vivo TNF-α production in response to lipopolysaccharide (LPS) exposure.[4,15,16] The downregulation of monocyte HLA-DR expression may in part explain the increased incidence of life-threatening nosocomial infections, including those considered reactivated or opportunistic, in patients following critical illness.[8,9,17,18]

The persistent expression of IL-10 is also believed to have a central role in immunoparalysis. Interleukin 10 is an antiinflammatory cytokine expressed by many cell types (T cells, B cells, dendritic cells, macrophages, and neutrophils) and capable of downregulating cytokine expression, antigen presentation, and costimulatory cell surface molecules preventing exuberant immune responses and autoimmunity.[19] There is an inverse linear correlation between L-10 serum concentrations and HLA-DR expression.[20] After cardiopulmonary bypass, those children with elevated IL-10 levels demonstrate ex vivo LPS hyporesponsiveness.[21] Following septic shock, in children who went on to develop persistent nosocomial infection, early plasma IL-10 levels were significantly higher than children with sepsis who did not experience nosocomial infections.[7] These children also demonstrated diminished TNF-α production ex vivo.[4] IL-10 is capable of suppressing T-cell cytokine production of IL-2 and INF-γ, meaning that IL-10 directly reduces adaptive immune responses.[22]

Like immunoparalysis, absolute lymphocytopenia has often been reported in previously healthy patients after severe sepsis, burns, neurotrauma, cardiopulmonary bypass, and viral infections.[23-28] Total lymphocyte counts measured in 22 children fell to a nadir at 6 hours after anesthesia for major surgery with minimal recovery at 48 hours.[25] Cardiopulmonary bypass further induced lymphocyte apoptosis compared with surgery alone.[26] A recent adult study assessed persistent lymphopenia as a biomarker for sepsis-induced immunosuppression and found that moderate to severe persistent lymphopenia on Day 4 following the diagnosis of sepsis predicted early and late mortality.[27] In a pediatric population, prolonged lymphopenia defined as lymphocyte count less than 1000 cells/μL for more than 7 days was associated with a greater than sixfold increased risk of death.[28]

The reasons for persistent lymphopenia are not understood, and one hypothesis is that elevated endogenous corticosteroids induce lymphopenia (see also Chapter 81). Exogenous corticosteroids have long been known to induce lymphocyte apoptosis, and critical illness elicits a hormonal stress response increasing endogenous corticosteroids, although there is no direct correlation between cortisol levels and lymphopenia.[23,28] In contrast, prolactin has been shown to affect lymphocyte survival, required for proliferation and prevention of steroid-induced apoptosis.[28] Drugs used in critically ill patients may contribute to lymphopenia by interfering with prolactin levels. Dopamine inhibits prolactin release, even at very low doses, and reduced prolactin levels directly affect lymphocyte function and survival.[28-30] Prolonged suppression of prolactin is associated with lymphopenia, nosocomial infection, and death.[28]

Several investigators have attempted to reverse immunoparalysis to reduce late infections and enhance patient survival.[6,31-37] Monocytes can be stimulated by granulocyte-macrophage colony-stimulating factor (GM-CSF). In nine consecutive healthy adults with immunoparalysis documented after LPS injection, 5 μg/kg of GM-CSF produced a fourfold increase in mean HLA-DR expression in peripheral blood monocytes and a ninefold increase in TNF-α response to LPS in as little as 24

hours.[32] When given to septic patients with acute respiratory distress syndrome (ARDS), GM-CSF was associated with improved gas exchange and increased neutrophil respiratory burst.[33] An observational study, followed by a prospective, randomized, open-label use of GM-CSF, demonstrated reversal of immunoparalysis in all seven of the children randomized to the GM-CSF group and none experienced a nosocomial infection.[7] However, a meta-analysis performed on 12 randomized controlled trials of either G-CSF or GM-CSF in sepsis found no impact on all-cause mortality, but there was a benefit in reversal of infection.[34] These studies did not require documentation of immunoparalysis before enrollment. A small, multicenter, double-blind, randomized control trial in which only patients with documented low HLA-DR levels were randomized to receive GM-CSF showed significant improvement in days of mechanical ventilation and severity of illness score but nonsignificant changes in ICU and hospital length of stay.[35] Interferons, which are major activators of monocytes, have also been administered in patients with sepsis to reduced immunoparalysis.[31] Exogenous interferon gamma-1β therapy was administered to 10 consecutive patients with less than 30% HLA-DR expression and restored both HLA-DR expression and production of IL-6 and TNF-α.[36] Aerosolized interferon-γ when administered to trauma patients with immunoparalysis (defined as suppressed HLA-DR expression on alveolar macrophages) was associated with a lower incidence of ventilator-associated pneumonia.[37] Additional clinical trials of interferon and GM-CSF are ongoing.[5]

Malnutrition and Immune Function

Worldwide, protein-calorie malnutrition is the most common cause of acquired immunodeficiency (see also Chapter 87).[38,39] Nutrition influences the course of HIV and TB, susceptibility to infection in older patients, the body's ability to respond to vaccines, and many other aspects of immune function.[40-43] Critical illness often causes initial hypermetabolism followed by macronutrient and micronutrient malnutrition. A significant proportion of children admitted to ICUs (even in affluent countries) have been noted to be malnourished, whereas many others will receive inadequate nutritional support during their stay in the ICU, implying that many critically ill children will have abnormal immune function secondary to nutritional deficits.[40,44-46] It is estimated that one in every five children admitted to the PICU presents with chronic malnutrition or will develop acute malnutrition.[40,47,48] Malnourished children and infants have greater numbers of ventilator days, longer ICU stays, increased hospital costs, and increased infectious complications.[47-49] Immune system dysfunction occurs so early in the course of malnutrition that measures of immune competence, such as anergy and total T-lymphocyte numbers, are sensitive indicators of a patient's nutritional status.[41]

Protein-energy malnutrition (PEM) is generally only studied in humans in its severest form. Although mice with PEM demonstrate hyporesponsive to LPS in expression of TLR-4 and co-receptor molecules on macrophages, extrapolation of animal data to humans may be inappropriate because of interspecies variability in immunoglobulin synthesis and cytokine regulation.[41,50] Protein-energy malnutrition increases the risk of bacterial colonization by altering mucosal defenses to pathogens, epithelial cell membrane glycoprotein receptor production, mucus production, and immunoglobulin A secretion.[43] Protein-energy malnutrition also

affects immune cells by delaying neutrophils mobilization, reducing natural killer cell lytic activity, and impairing T-lymphocyte function and proliferation.[51] The severity of PEM is proportional to the impairment of T-lymphocyte function, but all of the factors stated earlier increase a patient's susceptibility to infectious complications. Greater reduction in immune responses occurs when the malnutrition is more prolonged and severe, as reflected in decreased immunoglobulin levels and cytokine production (interferon-γ).[52]

Many specific nutrients are vital to immune function. Adult studies demonstrate improved clinical outcomes in the setting of acute respiratory distress syndrome (ARDS) and severe sepsis when patients are given an enteral formula containing antioxidants plus essential fatty acids.[53-55] The ω-3 polyunsaturated fatty acids (PUFAs), eicosopentaenoic acid and docosahexaenoic acid (DHA), synthesized from alpha-linolenic acid or obtained from a diet of fish, suppress lymphocyte responses to mitogen stimulation.[38,56] By definition, essential fatty acids, linoleic and alpha-linoleic acids, cannot be synthesized by mammalian cells and must be obtained through the diet. Linoleic acid is found in typically fish, shellfish, plant seeds/oils, and tree nuts.[56] For children in many parts of the world, access to fat other than cow's milk is severely limited.[38] Accumulating evidence suggests that dietary supplementation with ω-3 PUFAs is a "natural" immunosuppressant and may be useful in autoimmune diseases such as lupus erythematosus, rheumatoid arthritis, and diabetes mellitus.[56] Moderate ω-3 PUFA intake can enhance the immune response; for example, supplementation of infant formula with a small amount of DHA accelerates development of T-cell responsiveness in preterm infants (see also Chapter 87).[57] Studies have assessed children with acute lung injury and severe burns with associated acute respiratory failure who were treated with enteral formulas containing antioxidants and PUFAs. These investigations demonstrated formula tolerance, increased antiinflammatory biomarkers, improved oxygenation, and improved pulmonary compliance.[58,59] These studies were not designed to assess clinical outcomes.

There are many specific micronutrients identified as vital to immune function. Vitamin A has essential functions in immune cells and indirectly contributes to protection from infection through maintenance of vital epithelial cell differentiation and barrier function of the lung and intestine.[60] Vitamin A deficiency occurs in an estimated 100 million children worldwide and is a risk factor for increased death from pneumonia and diarrhea.[44,60] A survey of hospitalized children in Malawi reported that one-third had severe vitamin A deficiency and one-third had moderate deficiency.[61] Paradoxically, these children exhibited preferential monocyte synthesis of TNF-α as compared with IL-10. The underlying disease that prompted hospitalization possibly triggered this shift. Results of several randomized, double-blinded, placebo-controlled trials conducted in malnourished children have shown improved antibody response to vaccines and fewer diseases of the gastrointestinal and respiratory systems after vitamin A supplementation.[44,60,61] Vitamin A supplementation in individuals who are not deficient has no benefit, whereas high retinal levels are associated with an increase in diarrhea and pneumonia.[62]

Vitamin C (ascorbic acid) is highly concentrated in leukocytes, and low leukocyte vitamin C concentrations are associated with reduced immune function.[57] Epidemiologic data suggest that higher vitamin C consumption lowers the risk of cancer and cardiovascular disease, but despite numerous clinical trials with

participants of both sexes and varying ages, no definitive evidence that vitamin C supplementation reduces the frequency or symptoms of upper respiratory infections exists. High-dose vitamin C does improve several measures of immune function and does not appear to have any side effects.[44]

Vitamin D receptors are found on numerous immune cell types.[63] Vitamin D deficiency is associated with depressed macrophage function and impaired delayed hypersensitivity.[63] Although vitamin D deficiency has been documented as present on admission in many ICU patients, an association between low vitamin D levels and length of mechanical ventilation and mortality has been shown in some but not all studies.[64-71] In critically ill children, deficiency of vitamin D was more likely to occur in winter, in older children, and in those with darker skin.[64] A correlation between vitamin D levels and severity of illness in septic shock was identified.[64] Patients who were receiving vitamin D supplementation before admission had higher serum concentrations that appeared to be protective.[64] Vitamin D supplementation appears to be inexpensive, easily accomplished, and without risk, but to date there is no convincing evidence that vitamin D supplementation after the development of critical illness improves outcomes.[69,70,72,73]

Vitamin E (alphatocopherol) is a potent lipid-soluble antioxidant. Study results of vitamin E supplementation ranging from 200 to 800 mg/day in healthy adults showed increased CD4/CD8 ratios, mitogen responsiveness, antibody production, and decreased free radical production; however, a dosage of 300 mg/day for 3 weeks resulted in suppressed bactericidal activity in humans.[41] Optimal daily requirements of these nutrients in health and disease remain to be determined.

Of the trace elements that may affect the immune system, selenium, zinc, and iron have been the most widely studied. Selenium balances redox states and suppresses inflammation through its vital role in several antioxidant enzymes and intranuclear factors, including the glucocorticoid receptor, activator protein-1, and nuclear factor-κB.[41] In HIV infection, selenium supplementation modifies cytokine release, decreasing TNF-α and IL-8 while increasing IL-2.[74] Selenium improves T-cell proliferation and differentiation; however, selenium supplementation had no impact on severe sepsis in surgical ICU patients.[75] A single-center study of plasma selenium levels in children with systemic inflammatory response syndrome found an association among low selenium levels, inflammation, and nutritional status.[76] Enterally fed children whose selenium levels increased by Day 5 had greater ventilator-free days and ICU free days than those who did not.[77] Plasma selenium responds to adequate nutritional intake, but excessive selenium intake is toxic to the immune system and other organs.[41]

Zinc, as with selenium, is required for the activity of more than 100 enzymes.[78] Zinc supplementation increases the number of $CD4^+$ T cells; thus the CD4/CD8 T-cell ratio is improved. Zinc deficiency has been documented in alcoholics and in patients with burns and gastrointestinal disorders.[78,79] Zinc supplementation reduces bacteremia, hospitalization rates, and vaso-occlusive crises in patients with sickle cell anemia.[41] In young children, zinc supplementation reduced the duration of diarrhea and frequency of respiratory infections.[41,78]

Worldwide, 20% to 25% of the population has iron deficiency, which results in impaired cell-mediated immunity, particularly in neutrophil and natural killer cell function.[79] Although an association between iron availability and susceptibility to certain bacterial infections exists, there is little evidence that iron supplementation to

deficient individuals inhibits immune responses or increases susceptibility to infections.[79]

Transfusions

Critically ill patients frequently receive blood transfusions, and modified immune responses have been observed (see also Chapter 93). Patients with cancer who receive transfusions at the time of resection have a greater risk of dying than those who do not.[80,81] In contrast, some patients who receive blood transfusions before transplantation have a lower incidence of rejection, although transplantation recipients who have received mismatched HLA-DR blood products have accelerated graft rejection.[82] The long-term effects of transfusions on the immune system and disease susceptibility are not well understood, but even 19 years after transfusion, blood product recipients have fewer peripheral T lymphocytes, particularly helper T cells, than patients who did not undergo transfusion.[83] Transfusions after trauma or cardiopulmonary bypass are associated with increased infections; however, in major surgery or trauma, it is difficult to sort out the effect of transfusion versus the effect of surgery or trauma.[84]

Immunosuppressive Medications

The use of medications to alter immune responses is becoming common in clinical practice, treating broad categories of diseases, such as autoimmune disorders, allergic disorders, transplant rejection, and graft-versus-host disease.[51] Broadly, drugs used for immunosuppression can be grouped into corticosteroids, cytotoxic drugs, calcineurin inhibitors, mammalian target of rapamycin (mTOR), and biologicals (monoclonal or polyclonal antibodies targeting cytokines or specific cell surface molecules of immune cells). A detailed description of all categories of immunosuppressive agents is beyond the scope of this chapter. The primary adverse effect of this drug class is the weakening of cellular immune responses, making the patient more susceptible to bacterial, fungal, and viral infections (acute, chronic, and reactivated). Glucocorticoids exert significant antiinflammatory activity. Glucocorticoids bind a cytosolic receptor, which then translocates to the nucleus of a cell affecting gene transcription. The overall impacts of glucocorticoid therapy are reduced cytokine production, lymphocyte anergy or apoptosis, impaired phagocytosis of neutrophils, and reduced bactericidal activity of macrophages.[51,85] This wide range of immune defects places the patient at risk for viral, bacterial, and fungal infections. Cytotoxic agents interfere with the synthesis of DNA of rapidly dividing cells. Common cytotoxic medications are cyclophosphamide, methotrexate, azathioprine, and 6-mercaptopurine. These medications inhibit T- and B-lymphocyte proliferation, as well as any other rapidly dividing cell. The major limitation of cytotoxic agents is their toxicity to other cells, such as hematopoietic cells, gastrointestinal mucosa, and skin cells. The inhibition of new adaptive immune responses, possible development of cytopenias, and mucosa/skin barrier deterioration place the patient at risk for bacterial and fungal infections.[51,85] Calcineurin inhibitors and mTOR medications inhibit the activation of IL-2, an essential cytokine and signaling cascade needed for T-lymphocyte activation and

proliferation.[51] Crippling T-lymphocyte activation and proliferation place the patient at risk for viral infections and lymphoproliferative disorders.[85] The biologicals are a relatively new class of immunomodulatory agents, and many of their effects are dependent on their target. One example is antithymocyte globulin, a medication that targets T lymphocytes via multiple epitopes and causes profound and prolonged periods of lymphopenia, which is associated with reactivation of latent viruses.

Uremia

Uremia is a condition common in critically ill children with acute or chronic renal disease. Many end-stage renal disease patients are dialysis dependent and are at risk for invasive microorganisms independent of their need for dialysis or vascular/peritoneal access devices.[51] Uremic patients experience increased incidence and severity of infections compared with the general population. Children undergoing chronic dialysis have mortality rates 30 times greater than the general population even when disparities in age, sex, race, and diabetes are taken into account.[86] Essentially, uremia and dialysis cause a state chronic immune activation, thus leading to a proinflammatory state and immune hyporesponsiveness characterized by reduced lymphocyte numbers, impaired NK cell function, reduced dendritic cell antigen presentation, and failure to generate antibody responses to administered vaccines.[87-89]

Infectious Agents Other Than HIV

In addition to HIV, viruses such as measles, influenza, and human T-cell lymphotrophic virus-1 can suppress the immune response.[90-95] Neutrophils of patients infected with measles are not activated and therefore cannot phagocytize and kill bacteria.[90] Lymphopenia has been associated with measles, influenza, respiratory syncytial virus (RSV), and two paramyxoma viruses that can infect monocytes.[91-94] Following these infections, mortality is often related to secondary infections.[94,95] Okada et al.[91] documented that the measles virus infected only a small number of lymphocytes but apoptosis occurred in noninfected lymphocytes. The duration of lymphopenia was age dependent and was most prolonged in infants. The same response was not observed in response to a live measles vaccine.[92] Absolute lymphocyte counts were lower in hospitalized RSV-infected patients than controls and were lowest in patients admitted to the ICU.[93] No mortality was observed, and lymphocyte counts recovered. In children infected with RSV and known immunodeficiency such as following cancer therapy, the development of lower respiratory tract infection was associated with profound lymphopenia (<100 cells/μL) and mortality was 31%.[94]

HIV Infection and AIDS

AIDS is a clinical syndrome resulting from infection by HIV-1 (and rarely HIV-2), an RNA retrovirus dependent on a reverse transcriptase for replication.[96] Surrounding the RNA and its reverse transcriptase are core proteins p24 and p18. A viral envelope is composed of the host cell membrane studded with glycoproteins gp120

and gp40. HIV enters cells by binding gp120 to the CD4, a cell surface glycoprotein expressed on helper T lymphocytes, macrophages, and dendritic cells. After gp120-CD4 binding, HIV entry into cells is aided by the presence of a host coreceptor, chemokines CCR5 on macrophages, or CXCR4 on other cell lines. After HIV replication, the host's helper T lymphocytes undergo apoptosis, resulting in severe impairment of both cell-mediated and humoral immunity. Because pediatric HIV infection is most commonly transmitted from mother to infant, the acquired immunodeficiency is occurring in a host whose immune system, unlike an adult's, is relatively naive and has developed little natural immunity.[96,97] This may in part explain the shorter time required for progression to AIDS after HIV infection in perinatally infected children when compared with children infected after the age of 2 years.[98,99] Antiretroviral therapy can effectively reverse this immune dysfunction.[100]

The diagnosis of HIV-1 infection in adults and children older than 24 months is accomplished by identification of antibodies specific to HIV-1 or HIV-2 viral proteins and confirmed by a second test using different methodology.[101] Because infants carry transplacentally acquired maternal antibodies, HIV infection in infants younger than 24 months must be documented by HIV DNA polymerase chain reaction (PCR) or HIV RNA assay.[101] Generally viral testing is repeated three times (between 14 and 21 days, 1 to 2 months, and 4 to 6 months of age) with sensitivity increasing over time.[101] High-risk infants should be tested at birth. The absence of HIV infection can be confirmed by serology at 12 to 18 months of age, but positive serology may still reflect maternal antibody and should be confirmed by nucleic acid assay.

In 2014, the US Centers for Disease Control and Prevention modified an earlier classification system for HIV infection ranging from indeterminate to asymptomatic to severely symptomatic (ie, AIDS) on the basis of age-specific $CD4^+$ T-cell counts. Stage 3 HIV infection or an AIDS-defining illness in the presence of HIV infection confirms the diagnosis of AIDs.[102] AIDS-defining illnesses include recurrent bacterial infections, fungal and/or mycobacterium infection, CMV disease, lymphoma, encephalopathy or progressive multifocal leukoencephalopathy, wasting syndrome, and associated malignancies.

These categories aside, there appear to be at least two patterns of response to HIV infection in untreated children.[99,103] Children younger than 4 years, especially those aged 1 year or younger, are more likely to have *Pneumocystis jirovecii* pneumonia (PJP); have severe progressive encephalopathy, wasting, or both; and die earlier. Older children tend to have a less serious course, characterized by recurrent bacterial infections, LIP, nephropathy, and thrombocytopenia. The time course for vertically transmitted HIV infection to progress to AIDS in children is variable and may be more than 10 years; however, in children, AIDS is most commonly seen between 5 and 8 months.[100,104] The density of CCR5 receptor on nonactivated T cells correlates with the decline of $CD4^+$ T cells and prognosis.[105]

Globally, at the end of 2013, the adult prevalence of HIV was 0.8%.[103] Ninety-six percent of individuals living with HIV reside in low- and middle-income countries. Sub-Saharan Africa had the highest incidence of HIV infection, accounting for 70% of the world's cases with young women two times more likely than men to be infected.[104] East Africa and Central Africa have reduced the prevalence of HIV infection through educational programs. In Western Europe many new cases of HIV/AIDS are reported from persons who emigrated from or traveled to countries with a high HIV prevalence.[104]

As of December 2013, 3.2 million children are living with HIV worldwide, of which 240,000 were newly infected and 190,000 died annually.[104] Ninety-one percent of children living with HIV reside in sub-Saharan Africa.[104] Vertical transmission of HIV infection from untreated mother to fetus occurs at a rate of 20% to 35% but is reduced by 66% when antiretroviral therapy monotherapy (zidovudine [ZDV]) is taken during pregnancy, delivery, and the neonatal period.[106] Even though simple inexpensive monotherapy can reduce vertical transmission by 40% to 50%, only 33% of infected pregnant women receive treatment.[106] When used in combination with elective cesarean delivery and formula feeding, perinatal antiretroviral therapy has reduced the vertical transmission of HIV to less than 2% in the United States. Currently trials suggest that highly active antiretroviral therapy (HAART) in pregnancy may be more effective in preventing transmission than monotherapy.[107,108] It may also be important to extend antiretroviral therapy for the mother during the period of breastfeeding.[107,109,110] Although there has been extensive development of appropriate therapies, a major challenge has been prevention of mother-to-child transmission.[106,111-113]

Combinations of HAART used to treat HIV-infected patients have dramatically decreased mortality caused from HIV-associated conditions and opportunistic infections. The number of people living with HIV receiving HAART in 2013 is 12.9 million, but two-thirds of those who need it still have no access to drug.[104] Ninety percent of HIV-infected children live in sub-Saharan Africa and underdeveloped countries of Asia.[104] Because of cultural, economic, and political factors, HIV prevention and treatment have been slowly introduced in resource-limited regions. In Malawi, without antiretroviral therapy, the mortality rate at 3 years of age for HIV-infected children reached 89%.[114] This high mortality rate may be related to the burdens of infectious diseases and malnutrition and is seen in other parts of the world as well. The care of these children is complicated by overcrowding, limited access to clean water, and malnutrition. These conditions contribute to the high frequency of TB, cytomegalovirus (CMV), hepatitis, and gastroenteritis seen in this population. Still there is growing evidence that antiretroviral can be provided successfully to children in resource-limited settings.[115,116] Even in this environment, the efficacy of early initiation of antiretroviral HIV therapy in children reduced mortality rates by 75%.[116] In the United States 75% of HIV-infected children are alive at age 5 years.[117] Most data regarding outcome and survival of HIV-infected children presented in this chapter are drawn from patients who did not receive antiretroviral therapy from the time of birth and may have never received it. Such data are still applicable to underdeveloped countries, given that only one in three adults and one in four children receive HAART despite a global increase in HAART access from 7% in 2003 to 42% in 2008.[104]

As of February 2014, thirty-one HIV antiretroviral agents were approved and available for use in the United States; 17 have a pediatric indication.[101] Because resistance develops with monotherapy, multiple drug regimens known as HAART are used in children and adults.[101] There are five classes of agents available and three drugs are typically selected from at least two classes. Measurement of both HIV-1 viral load (by RNA PCR) and the number of $CD4^+$ T cells is performed to monitor the effectiveness of HAART.[101] Baseline viral loads are higher in children than in adults and have a slower decay rate after the introduction of HAART.[118] Pediatric studies in which dosage adjustments were directed by pharmacokinetics resulted in superior

decreases in viral loads compared with fixed dosages based on weight.[101] Each antiretroviral therapy has its own toxicity and potential for drug interactions. Antiretroviral therapy is rapidly evolving and should be directed by a specialized practitioner.[101] Older HIV-infected adults are age 50 years or older, and this population comprised 25% of the HIV-infected population in the United States in 2007.[118] HIV-infected patients are living longer and developing non–HIV-associated comorbidities. It is estimated that by 2015, more than 50% of living HIV-infected patients in the United States will be older than 50 years.[118]

While the rate of hospitalizations decreased for HIV patients with HAART, the rates of ICU admission have not changed and in some studies increased.[118,119] Nearly 20% of hospitalized HIV-infected patients require transfer to the ICU.[119] Barbier et al.[120] identified major changes in the clinical presentation, ICU management, and mortality of critically ill HIV-infected adults from 1999 to 2010. AIDs-defining opportunistic infections decreased while non–HIV-associated comorbidities increased.[120] The use of life-sustaining therapies also increased, and there was a marked decrease in short-term mortality in HIV-infected patients needing aggressive therapies.[120] Mechanical ventilation support remains to be the predominant support modality for HIV-infected adults and children.[118-121]

Pulmonary Complications and Respiratory Failure

Pulmonary complications remain the most frequent indication for admission of children with AIDS to an ICU.[121-123] Pneumonia is the leading cause of morbidity and death in HIV-infected children worldwide.[121] Comparing low- or middle-income countries to high-income countries, pneumonia accounts for 20% of the annual deaths in children versus 4.3%, respectively.[121] Comparing HIV-infected children on HAART with uninfected children, pneumonia is more likely to be severe with high treatment failure rates and increased risk of death.[121] Bacterial pneumonia is common in this population.[117,124,125] Along with the usual pathogens frequently seen in childhood, such as *Streptococcus pneumoniae* and mycoplasma, immunodeficient children are also susceptible to pseudomonal and staphylococcal infections.[107,126] The incidence of *Haemophilus influenzae* infection is declining where vaccination is available, and immunization against pneumococcal infections has been associated with a significant drop in pneumococcal disease in HIV-infected children.[125] Empiric therapy for pneumonia in such children should cover the most common pathogens and be based on hospital-specific susceptibility profiles, but it is important to note that children with HIV infections may not respond to standard antibiotic therapies for lower respiratory tract infections.[127]

Initiation of antiretroviral therapy can result in rapid immune recovery. A subset of patients experience an inflammatory response as the immune system is reconstituted.[128] Most cases have another occult infection in addition to HIV. In one study, nearly 50% were associated with mycobacterial infections such as *Mycobacterium avium-intracellulare* and herpes viruses such as *Varicella zoster*.[129] Clinical presentation is related to the focus of infection. Enhanced screening and subsequent treatment of opportunistic infections such as TB before beginning HAART may prevent the reconstitution inflammatory syndrome. The World Health

Organization has recommended prednisone for patients with TB who experience severe paradoxical reactions. However, there are no randomized controlled trials to support this practice.[128]

Pneumocystis Jirovecii Pneumonia

Pneumocystis jirovecii pneumonia (PJP) occurs in patients with acquired immunodeficiency from HIV, chemotherapy, and immunomodulatory therapies. Although increased emphasis on early prophylaxis has reduced its incidence, PJP is still the most common AIDS-defining illness in pediatrics.[127,130,131] Infants not previously recognized to be infected with HIV may present as early as 3 to 4 weeks of age, whereas the median age or presentation to ICUs is between 3 and 6 months of age and coincides with the timing of a natural decline in maternal antibodies.[123] In children known to be at risk of HIV infection, PJP prophylaxis is indicated starting at 4 to 6 weeks of age as $CD4^+$ T-cell counts obtained before the development of infection are not predictive of infection and can drop precipitously.[102] *P. jirovecii* is unique to humans and has a predilection for the lung.[132] PJP generally presents with cough, fever, tachypnea, and dyspnea of several days' duration.[132] Physical examination typically reveals retractions, grunting, rales, rhonchi, or wheezing. The chest radiograph generally shows diffuse interstitial infiltrates, but pulmonary infiltrates can be variable in children, in part because infants have a greater propensity for atelectasis.[132,133] Hypoxemia is often out of proportion to clinical and radiographic examinations. A selectively elevated serum lactate dehydrogenase level is suggestive, although not diagnostic of, PJP.[132] For a confirmation of a PJP diagnosis, bronchoalveolar lavage should be performed. Flexible fiberoptic bronchoscopy has a diagnostic yield of 90% to 97% and allows one to look for other pathogens as well.[132,134] Nonbronchoscopic bronchoalveolar lavage and sputum induction can also be used in combination with PCR to detect PJP.[134,135] Patients in whom no diagnosis is obtained from bronchoalveolar lavage should undergo an open lung biopsy. This procedure has a diagnostic yield for PJP of 97% in the study of patients with underlying malignancy or immune suppression.[132]

The preferred antiprotozoal therapy for PJP is the combination of trimethoprim and sulfamethoxazole (TMP-SMX) (20 mg/kg/day trimethoprim).[132] Patients in whom this combination agent fails have not been shown to respond to a change in antiprotozoal therapy. In fact, higher doses of both components may be required to achieve therapeutic levels in critically ill patients.[132] Sulfa allergy as manifested by severe drug eruptions including Stevens-Johnson syndrome is less frequent in children than in adults; however, this complication may prompt a change to therapy with pentamidine isethionate (4 mg/kg/day). When adverse events such as pancreatitis and renal failure occur as a result of pentamidine, atovaquone (40 mg/kg/day) is an alternative treatment.[132] Twenty-one days of therapy are followed by prophylactic therapy, for which TMP-SMX is also the agent of choice. For patients allergic to sulfa, PJP prophylaxis can be achieved with pentamidine, dapsone, or atovaquone, although these agents have not been rigorously studied in children.

Several adult randomized controlled trials showed efficacy of high-dose steroids in HIV positive adults with moderate PJP.[128] Although no controlled studies have been performed in children, improved outcomes in children who received corticosteroids have been described in several case series.[136-139] Even in the face of

respiratory failure, the survival rates reported with adjunctive corticosteroids therapy are 91% to 100% in a limited number of children.[136,137] Adults who have respiratory failure despite adjunctive corticosteroids have a high risk of death. Failure to improve after 5 days of mechanical ventilation and the development of pneumothorax were strongly predictive of death in adults.[140]

Pneumocystis pneumonia has also been reported in patients receiving high-dose steroids, transplant-related immunosuppression, and the new monoclonal antibodies that modulate the immune system.[132] Pneumocystis pneumonia presents differently in non–HIV-infected patients. The onset of the disease may be more abrupt. The mortality is greater in cancer patients than AIDs patients, and corticosteroids are not as clearly beneficial.

Cytomegalovirus Pneumonitis

Children at risk for vertical transmission of HIV are also at risk for CMV infection. Kitchin et al.[141] reported that 55% of HIV-exposed but untreated children with respiratory failure in South Africa had a CMV viral load in the range consistent with CMV disease. Furthermore, the mortality from CMV with and without PJP was over 40%[141] despite empiric treatment with ganciclovir in all cases; failure of PJP response to conventional therapy may be evidence of concomitant CMV infection. Pneumonitis from CMV is also a common complication of solid organ and hematopoietic stem cell recipients. The presentation of CMV pneumonitis can closely mimic that of PJP with diffuse interstitial infiltrates and hypoxemia, but there is generally a more insidious onset; however, some reports of a more fulminant course exist.[142]

While the definitive diagnosis of CMV pneumonitis may require identification of characteristic intracellular viral inclusion bodies in pulmonary macrophages or biopsy specimen, because viral shedding is known to occur, the prevalence of CMV pneumonitis and its contribution to mortality in immunocompromised children have led many to recommend empiric therapy for pneumonia.[141-143] Viral culture and viral nucleic acid detection by PCR performed on tracheal aspirates and blood have all been used to guide treatment.[140-142] The treatment for CMV disease is ganciclovir 5 mg/kg given twice daily followed by long-term viral suppressive therapy.[144,145] Foscarnet and cidofovir have been used in other immunosuppressed patients, but these drugs have significant nephrotoxicity.[144,145] Although solid organ transplant recipients receive prophylaxis against CMV disease with ganciclovir, this approach has not been applied to patients with AIDS. Of course, patients with AIDS should also receive HAART.

Other Viral Pathogens

Children with AIDS are more likely to experience lower respiratory tract disease and pneumonia when contracting RSV and influenza.[146-148] For RSV, the estimated incidence of lower tract disease was twofold greater in HIV-infected children; it is not clear that HIV infection increases the likelihood of death.[148] The incidence of lower respiratory tract disease requiring hospitalization in influenza was eightfold higher in children with HIV infection.[147] HIV-infected children with influenza pneumonia were older and more likely to have another underlying disease or

concurrent infection. Despite these comorbidities, there was no difference in clinical outcome. Other pathogenic viruses recovered from pediatric patients with AIDS include adenovirus, parainfluenza, herpes simplex, and measles. In vitro data suggest ribavirin and cidofovir may be effective against some of these viral pathogens; however, evidence of in vivo efficacy is limited to anecdotal reports in immunosuppressed patients.[149-151] Immunosuppressed children have been noted to shed viral pathogens such as RSV and influenza for a prolonged period, and therefore nosocomial viral infections may be a significant problem if infection control practices are not maintained.[151,152]

Mycobacterial Pathogens

Worldwide, approximately one-third of the human population is infected with the *Mycobacterium bacillus.*[153] Most of these individuals live in developing countries where the prevalence of HIV infection is high. The incidence of *M. tuberculosis* appeared to level off in the United States by 1985 but began rising steadily in 1988—an increase attributed to the AIDS epidemic.[154] The increased incidence of pediatric TB is likely due to increased exposure to adults with active infection. HIV-infected children with TB have higher CD4+ T-cell counts than those observed with other classic opportunistic infections.[100] Although adults generally acquire HIV infection after acquiring TB, the opposite is true in children. Thus the HIV-infected child never has a chance to mount an immunologic response to *M. tuberculosis*. In contrast to adults who have apical, cavitary lesions, children have more peripheral disease.[153] Most pediatric patients with AIDS have diffuse infiltrates consistent with LIP or PCP.[153,154] These children also have a high incidence of extrapulmonary manifestations such as hepatosplenomegaly and meningitis.

Aggressive efforts to confirm mycobacterium infection by culture are required because anergy obscures Mantoux testing, as well as the development of pleural effusions and localized lymphadenopathy. Use of PCR to identify *M. tuberculosis* nucleic acids in bronchoalveolar lavage and cerebrospinal fluid (CSF) specimens can accelerate diagnosis of this infection.[129,155] Recovery of mycobacterium by sputum induction has been reported in infants and very young children.[156] In some regions, organism recovery is necessary for antimicrobial susceptibility determination; 25% of isolates are resistant.[129,153,157] In countries where the diagnostic approaches are not readily available, it is useful to obtain radiographs of family members.[129]

Pending sensitivity reports, treatment of TB is initiated with a five-drug regimen.[158,159] The presence of multidrug resistance increases the likelihood of death. These patients should simultaneously be treated with antiretroviral therapy; however, rifampin is contraindicated with protease inhibitors and nonnucleoside reverse transcriptase inhibitors.[158] During HAART, reconstitution of the immune system may increase the inflammatory response to pulmonary TB. Children with TB and HIV infection who are not treated with HAART have a higher mortality rate than children not infected with HIV.[158] They must be treated for a longer time, perhaps because of poor drug absorption and a weakened immune system.[158]

M. avium-intracellulare complex (MAC) can also be recovered from the lungs of children with pneumonia.[122] Colonization is difficult to differentiate from invasive disease. Treatment options include coverage with clarithromycin in combination with ethambutol, rifabutin, or amikacin. Primary prophylaxis once a week with

azithromycin is recommended in children older than 2 years and younger than 1 year with CD4 counts persistently below 75. Children between 1 and 2 years of age should receive prophylaxis for CD4 counts less than 50.[101]

Fungal Infections

Candida is frequently recovered from sputum and bronchoalveolar lavage samples in children with AIDS.[160] Candidiasis of the respiratory or gastrointestinal system is an AIDS-defining illness.[105] Aspergillosis has also been reported in older children with multiple opportunistic infections, prolonged hospitalization, neutropenia, and corticosteroid use.[161] Cryptococcosis occurs in 5% to 15% of adults but in only 0.6% to 1% of children.[161] This ubiquitous organism enters the body through the respiratory tract. Therefore initial symptoms are generally both pulmonary and nonspecific. Recommended therapy is amphotericin B in combination with 5-flucytosine (100 mg/kg/day) for 2 weeks followed by fluconazole (12 mg/kg/day divided in two doses) for 8 additional weeks.[162] Cryptococcal antigen titers are useful in the evaluation of possible relapse. Prophylaxis for the prevention of cryptococcal disease is not recommended in children. Fusariosis has been reported in neutropenic patients with AIDS. Other fungal infections such as histoplasmosis, cryptococcosis, coccidiomycosis, and disseminated *Penicillium marneffei* are reported in patients with AIDS who are living in or traveling through endemic areas.[122,162]

Lymphoid Interstitial Pneumonitis

LIP is a lymphoproliferative disorder associated with viral infections. In children LIP is almost exclusively seen with Epstein-Barr virus (EBV) and HIV.[163] LIP occurs in 30% to 50% of pediatric patients with AIDS, presenting in the second year of life in that patient population with high antibody titers and recurrent bacterial infections. Generally the children also have diffuse lymphadenopathy and hepatosplenomegaly. Children with LIP may have mild pulmonary symptoms such as dry cough but generally are admitted to the pediatric ICU only when an acute infection is superimposed on their chronic condition. When such is the case, maximal therapy of the acute exacerbation is indicated, including mechanical ventilation. On chest radiograph hilar adenopathy and reticulonodular infiltrates are seen. Pulmonary function tests reveal reduced lung volumes and diffusing capacity. Histologically, peribronchial lymphoid nodules containing plasma cells and lymphocytes are observed. Most specimens show predominantly $CD8^+$ T cells.

Spontaneous radiographic resolution was reported in 65% of children with LIP.[164] Patients with hypoxemia are treated with steroids, and resolution is seen in most patients in 2 to 4 weeks. If the patient is persistently febrile, MAC infection should be ruled out before steroid administration.[122]

Upper Airway Obstruction

Young children and infants exhibit upper airway obstruction with greater frequency than adults. Whereas classic viral laryngotracheitis is the most common cause in the immunocompetent patient, immunocompromised patients are susceptible to a greater variety of infectious entities, including bacterial tracheitis, CMV-related

ulceration of the trachea, and *Candida* infections of the airway oropharynx.[165,166] The clinical course in HIV-infected children is different with many requiring tracheostomy.[166] Although in the general population *Staphylococcus aureus* is the most commonly reported cause of bacterial tracheitis, *Pseudomonas* species are a frequent cause of tracheitis in patients with AIDS.[166] Given the complexity of the differential diagnosis of stridor in this population, early laryngoscopy and bronchoscopy are indicated.

Cardiovascular Complications

Septic Shock

After the introduction of PJP prophylaxis, severe sepsis became the most common reason for ICU admission in patients with AIDS.[118] A systematic review demonstrated community-acquired bacterial bloodstream infections occurring of hospitalized HIV patients at 20% and 30% in adults and children, respectively.[167] The main pathogens identified were nontyphoidal salmonella, *Streptococcus pneumoniae, Escherichia coli,* and *Staphylococcus aureus*.[167] Regional differences were noted especially for *S pneumoniae,* likely due to vaccination availability and combinational antiretroviral therapy access.[167] HIV-infected patients do appear to be more susceptible to *S. aureus* and *Pseudomonas* infections.[168] In one series of pediatric patients with AIDS, 10% of patients had gram-negative bacillary bacteremia with a risk of death that was greater than 40%, and *Pseudomonas* sepsis accounted for 26% of these episodes.[168] *Pseudomonas* infection is frequently associated with neutropenia, which may be a cause or effect phenomenon.[168]

Vasculitis

Vasculitis has been reported in patients with HIV infection, but it is not clear if HIV causes the condition or is merely an association, although there are a variety of suggested mechanisms.[169-175] Many infections reported in HIV-infected patients, including herpes viruses and mycobacterium, can cause inflammation by direct infection or an immune-mediated response. The most frequently involved organs are skin, peripheral nerve or muscle, and the central nervous system (CNS).[169] Several cases of polyarteritis nodosa have been reported.[169] When vasculitis is noted, an infectious agent should be sought.[176] The authors have observed an increased incidence of arterial catheter complications among HIV-infected children, and it is probably wise to exercise caution in the use of central venous and arterial catheters in HIV-infected children.

Myocardial Dysfunction

Cardiac dysfunction develops in 19% to 25% of HIV-infected children and is the presenting sign in a minority of children.[177,178] About 10% of a survey population had chronic congestive heart failure, whereas another 10% had transiently decreased ventricular function.[179-181] Cardiac complications appear to occur more frequently in rapidly progressing patients with encephalitis and other AIDS-defining illnesses. Because tachycardia and hepatomegaly are so common in pediatric AIDS patients

with fever, pulmonary infection, and anemia, a clinical diagnosis of cardiac involvement is difficult to make. Enlargement of the cardiac silhouette may not be appreciable even in patients with significant muscle hypertrophy or pericardial effusion. Given these inherent difficulties in the detection of cardiac disease, assessment of a critically ill child with AIDS should include echocardiography. When assessment is prospectively followed by echocardiography, the earliest sign of cardiac involvement is diastolic dysfunction.[178] At autopsy, aside from biventricular dilation, macroscopic evidence of cardiac dysfunction has been difficult to find in adults or children. Microscopically, in a limited number of cases, lymphocytic infiltrates are observed, but actual cardiomyocyte necrosis is rare.[182] Mild foci of lacy interstitial fibrosis may also occur.[179,182] True cardiomyocyte inflammation or myocarditis is rare in children.

HIV cardiomyopathy likely has several causes. Direct evidence of myocardial infection by HIV-1 has been documented by culture, Southern blot test, and in situ hybridization,[179,182] but it is unclear if the myocytes, which express no CD4 receptors, actually harbor HIV. Coxsackie B3 virus, CMV, adenovirus, EBV, and *Toxoplasmosis gondii* have also been identified as pathogens causing myocardial dysfunction.[183-185] Of 32 HIV-infected children who died, 7 had evidence of CMV infection and 10 had evidence of adenovirus infection by PCR performed on myocardial tissue.[185] Selenium deficiency has been documented in severely malnourished children with AIDS whose cardiac function improved after selenium supplementation.[186]

In the ICU, patients with severe cardiac dysfunction respond to management of preload, increasing contractility, and afterload reduction. Endocarditis, myocardial ischemia, and other potentially treatable causes of cardiac dysfunction should be ruled out with electrocardiography and echocardiography. Pharmacologic afterload reduction should be considered as first-line therapy, with digitalization and diuretic therapy as appropriate. Other than selenium supplementation there is no direct therapy available for HIV-related cardiomyopathy.[186] Agents that are associated with myocardial dysfunction, such as pentamidine, foscarnet, and dideoxyinosine (ddI), should be avoided.[184,185] A small population of patients has been noted to have transient cardiac dysfunction manifested by tachycardia and poor peripheral perfusion despite adequate filling pressures. This has been noted during PJP infection and may be related to cytokine release. Although survival data following clinically evident congestive heart failure in children undergoing HAART have not been reported, HAART intervention in children and adolescents appears to be cardioprotective.[187] The etiology of cardioprotective effects is incomplete, and evidence from adult studies links HIV infection as an independent risk factor in developing chronic cardiovascular conditions, such as hypertension, coronary artery disease, myocardial infarction, stroke, and pulmonary artery hypertension.[188,189] Prior studies demonstrate a potential association between congenital heart defects (CHDs), myocardial dysfunction, and zidovudine in utero exposure.[189] A current observational cohort study confirms the association between in utero exposure to zidovudine and CHD, with an adjusted odds ratio of 2.2; in addition, the randomized clinical trial (PRIMEVA) demonstrated an association between in utero zidovudine and long-lasting postnatal myocardial remodeling in girls.[190]

Dysrhythmias

In a survey of 81 HIV-infected children, dysrhythmias occurred in 35%, including atrial and ventricular ectopy, ventricular tachycardia, and ventricular fibrillation.[177,178] A syndrome of autonomic dysfunction has been reported in adult patients with AIDS, and similar lability in blood pressure and heart rate has been noted in a number of HIV-infected children. Catecholamine surges have been described in adults. Additionally, peripheral neuropathy may contribute to altered vascular regulation and a propensity for cardiac arrhythmias.

Pericardial Disease

Pericardial disease is reported in approximately 30% of HIV-infected children undergoing echocardiography or autopsy.[178,180] In five pediatric patients in whom fluid was cultured, no pathogens were identified. In 14 adult patients in whom fluid was obtained, atypical mesothelial cells were identified. One patient had lymphoma, one had histoplasmosis, and a third had CMV identified by a pericardial biopsy specimen. A pericardial effusion greater than 5 mm in diameter was detected in 5.4% of prospectively evaluated HIV-infected children, but no episodes of tamponade were reported.[191,192] Cardiac arrest due to tamponade has been reported in five adult patients with AIDS.[192]

Renal Failure

HIV-associated nephropathy (HIVAN) was first reported in 1983 and may often be the first manifestation of AIDS.[193-197] Complications from HIVAN generally arise between ages 2.5 and 4.9 years and appear to be more prevalent in children of African or Afro-Caribbean descent. The usual presentation of renal dysfunction is severe proteinuria (>3.5 g/day) with hypoalbuminemia and anasarca. This may be associated with renal tubular acidosis. Creatinine clearance is usually normal. Proteinuria may be accompanied by hematuria. Immunoglobulins are usually elevated while complement is normal. On ultrasound, the kidneys are enlarged. Biopsy specimens show focal and segmental glomerulosclerosis.[194] The course of the disease before HAART was usually fulminant, with end-stage renal disease developing in 8 to 9 months. Effective antiretroviral therapy slows or reverses the course of HIV nephropathy, but HAART is associated with renal toxicities.[195,196,198,199] Atypical hemolytic uremic syndrome or thrombotic microangiopathy is also described in pediatric patients with AIDS.[196,200]

Potentially nephrotoxic drugs to which the HIV-infected patient may be exposed are legion. Indinavir and tenofovir are associated with increased risk of chronic renal failure.[199,201,202] Pentamidine-induced renal toxicity usually occurs in the second week of therapy. Proteinuria and particularly hematuria, which may be falsely attributed to HIV nephropathy or catheter-induced trauma, are hallmarks of pentamidine toxicity. Early recognition of this complication and cessation of pentamidine increase the likelihood of recovery; rechallenge with the drug will prompt early return of proteinuria and hematuria. Toxicity from sulfadiazine during the treatment of toxoplasmosis is also reported and can be reduced by hydration.[200] Amphotericin-induced nephrotoxicity is particularly problematic when the drug is used in combination with aminoglycosides. Liposomal-encapsulated amphotericin B allows for higher doses with less toxicity.

In critically ill patients with AIDS, acute tubular necrosis may be precipitated by sepsis, hypovolemia, or hypoperfusion, which is reversible as in non–HIV-infected patients, although HIV-infected children have a higher in-hospital mortality when at admission they demonstrate acute kidney injury.[196,203] The same principles for management and support of a patient with reversible acute renal failure apply to the HIV-infected population. For patients who are seen in the ICU with end-stage renal disease due to HIV nephropathy, the indications for dialysis are the same as in other patient populations, but the decision to undertake dialysis must be made on an individual basis (see also Chapter 78). Peritonitis during ambulatory peritoneal dialysis in pediatric patients with AIDS does not occur with any apparent greater frequency than in immunocompetent patients.[204] Kidney transplant has been successful in carefully selected HIV-infected patients.[196,205]

Abdominal Complications

Patients with AIDS have multiple gastrointestinal complaints including dysphagia, abdominal pain, and chronic diarrhea, but these are generally not important in the ICU except that they affect nutritional status.[206] Other more life-threatening complications include severe dehydration, intraabdominal sepsis, pancreatitis, and hepatic failure (Table 104.1).

TABLE 104.1

Infectious Morbidity in Critically Ill Patients With Cancer

	Common	Less Common
Granulocytopenia		
Bacteria	*Staphylococcus aureus, Streptococcus pneumonia, Klebsiella, Pseudomonas*	*Enterobacter, Acinetobacter, Stenotrophomonas*
Fungi/molds	*Candida*, aspergillosis, zygomycosis	
Parasites		
Viruses		HSV1 or 2, VZV
Cellular Defects		
Bacteria	*Legionella, Nocardia*	*Mycobacterium tuberculosis*
Fungi/molds	*Pneumocystis, Cryptococcus, Mucormycosis*	
Parasites	*Toxoplasma*	
Viruses	CMV, EBV, adenovirus, VZV	
Humoral Defects		
Bacteria	*S. pneumonia, Haemophilus influenzae*	
Fungi/molds		*Pneumocystis*
Parasites		*Giardia lamblia*
Viruses		VZV
Combined Defects		
Bacteria	*S. aureus, S. pneumonia, Klebsiella, Pseudomonas*	*M. tuberculosis, Listeria monocytogenes, Legionella*
Fungi/molds	*Pneumocystis*, aspergillosis, *Cryptococcus*	Zygomycosis, mucormycosis
Parasites	*Toxoplasma*	
Viruses	CMV, VZV, influenza, parainfluenza, RSV, adenovirus	HSV 1 or 2

CMV, cytomegalovirus, *EBV*, Epstein-Barr virus; *HSV*, herpes simplex virus; *RSV*, respiratory syncytial virus; *VZV*, varicella-zoster virus.

Modified from Safdar A, Armstrong D. Infectious morbidity in critically ill patients with cancer. *Crit Care Clin*. 2001;17:531.

Diarrhea occurs in 40% to 60% of children with AIDS and may produce severe dehydration.[207] Worldwide, acute diarrhea is the most common cause of death in children with AIDS.[207] In underdeveloped countries where poor sanitation increases

the risk of diarrheal diseases, HIV-related hypovolemic shock is a common indication for pediatric ICU admission. Copious diarrhea is suggestive of small intestine involvement, whereas tenesmus suggests infection involving the distal colon and rectum. Diffuse enterocolitis produces a secretory diarrhea with profound volume losses. Patients with AIDS may have typical infectious enteritis and enterocolitis caused by *Salmonella, Shigella, Giardia, Campylobacter*, and rotavirus but may also have an atypical, more prolonged course.[206-208] The frequent use of systemic antibiotics in HIV-infected children results in *Clostridium difficile* colitis. *M. avium-intracellulare,* cryptosporidium, *Giardia, Isospora belli,* CMV, and adenovirus may all induce opportunistic small bowel enteropathy.[206-208] Patients with MAC, CMV, and *Candida* infection typically also have extragastrointestinal infection.[209] A nonspecific enteropathy may arise as a result of the overgrowth of normal gut flora due to the effects of local immunodeficiency and antibiotic use. It is not uncommon to find heavy growth of *Candida albicans* or *Pseudomonas aeruginosa* in stool cultures.

If findings from stool culture and analysis are negative, a flexible sigmoidoscopy with a rectal biopsy should be considered in the child with rectal bleeding, tenesmus, or both. Aspiration of duodenal secretions is particularly helpful in evaluation of patients from underdeveloped countries in that the aspirate may reveal infection with *I. belli, Cryptosporidium parvum,* or helminthic species. Additional evaluation may be desirable, including small bowel radiography or abdominal computed tomography (CT) scanning. If results of all diagnostic studies are negative, diarrhea may be due to HIV therapy because most antiretroviral agents are associated with diarrhea (Box 104.1).[210]

Protease inhibitors

Pentamidine

Recovery of MAC from the blood generally indicates invasive disease, but percutaneous needle aspiration with CT guidance of enlarged intraabdominal nodes may be confirmatory.[209,211] Antimicrobial therapy of disseminated MAC infection before HAART was unrewarding, and disseminated MAC was rapidly fatal. Current antimicrobial therapy is a double-drug regimen of clarithromycin and ethambutol with the possible addition of a third agent, including rifabutin, ciprofloxacin, or azithromycin. Prophylaxis against MAC with azithromycin is indicated in children with CD4 counts less than 75 cells/μL and in infants with counts less than 100 cells/μL.[212] In patients treated with HAART, diarrhea often persists despite improvements in immunologic function.[210]

Acute Abdomen

The evaluation and management of acute abdominal pain in HIV-infected children are complicated by their immunosuppressed state. Localized signs of infection can be masked by immunosuppression, debilitation, and previous or current use of antibiotics. In fact, a significant intraabdominal abscess may result in minor symptoms, with unremarkable elevations in white blood cell count or temperature. Thus diagnostic imaging with abdominal CT scan is invaluable for evaluation in this population. Although morbidity after surgical intervention is somewhat higher in patients with AIDS, there is still a significant survival when such intervention is undertaken promptly.[213-215] Gastric and proximal small bowel symptoms such as pain or bleeding may arise from stress gastritis and infiltrative processes caused by viruses, particularly CMV and adenovirus, *Giardia lamblia,* tuberculosis, and lymphoma. Supportive management of these conditions is the same as that for immunocompetent patients, although the appropriate antimicrobial therapy may be different.

Pancreatitis

Pancreatitis in the AIDS population results from both the disease and its treatment.[101,216-218] Infectious causative entities include CMV, adenovirus, mycobacterium, fungal infections, *Cryptococcus,* herpes simplex virus (HSV), and protozoal infections such as toxoplasmosis, *Pneumocystis,* and cryptosporidium. The list of drugs known to cause pancreatitis is extensive and includes the antiretroviral agent zalcitabine and the antiprotozoal agent pentamidine. The mechanism by which drugs induce pancreatitis is unknown.

Pancreatitis often goes undiagnosed. Autopsy findings reveal significant pancreatic lesions in approximately 10% of patients with AIDS, yet pancreatic lesions are rarely recognized during life.[216] Nine (17%) of 53 children seen at one institution demonstrated pancreatitis.[217] Four of five of these carried CMV. In one of these patients, CMV was cultured from pancreatic duct fluid. Six of nine had serologic evidence of EBV. Five children were receiving pentamidine at the time of presentation. Maintaining a high index of suspicion for pancreatitis is important because vomiting, abdominal distention, and malabsorption are common complaints in the HIV-infected child. Evaluation of these patients should include both serum

lipase and amylase determinations because parotid inflammation seen in HIV infection can cause isolated elevations of serum amylase concentrations. Abdominal ultrasound is only useful in the detection of a large edematous pancreas and in follow-up assessment for pancreatic pseudocyst.

Treatment includes bowel rest and hyperalimentation along with removal of the offending agent as in the case of drug-induced pancreatitis. In infectious pancreatitis, treatment of the underlying cause, while indicated, may not change the course of the disease.[217] Despite intervention, seven of eight reported children with pancreatitis had active or recurrent disease at the time of death. The mean survival time from onset to death was 8 months (range, 0.5-13 months).[217] In this patient population, anatomic abnormality is rarely the cause of pancreatitis and there is little role for surgical intervention.

Hepatobiliary Failure

The cause of hepatic failure in HIV-infected patients differs from that of other adults and is affected by the patient's degree of immunosuppression.[219] In early stages, hepatic disease is usually a result of drug toxicity or hepatotropic virus infections. Drug-induced hepatotoxicity has been reported with sulfa drugs, isoniazid, rifampin, and rifabutin.[219,220] Several antiretroviral agents can cause hepatitis.[101] If HIV progresses to AIDS, the liver manifests systemic involvement of opportunistic infections.[219,221,222] Reviews of hepatic tissue disease in HIV-infected children document that CMV and mycobacterial disease are common in children, whereas classic viral hepatitis is relatively rare.[219,223,224] As the immune system is reconstituted in response to HAART, hepatitis B can flare up.[210] Chronic hepatitis becomes clinically significant as survival increases in patients receiving HAART.[210] Cholangitis and cholecystitis are well described in adult patients with AIDS. Biliary tract infections have been attributed to CMV, adenovirus, cryptosporidium, and microsporidia.[222-225]

Liver biopsy is only indicated when mycobacterial disease is expected or jaundice is present, as most diseases can be diagnosed by serologic testing or PCR.[219] Drug toxicity has no specific biopsy finding. HIV itself can cause a giant cell hepatitis. Dense lymphoid infiltrates, similar to those in the lung in LIP, are also described. Adenovirus, CMV, and HSV and other opportunistic infections can cause acute jaundice and hepatitis with fever.[221,223-228] Hepatitis B and C can occur in patients with HIV/AIDS, and it is estimated that 30% of HIV-infected adults worldwide are coinfected with hepatitis C.[210,229] In certain established diagnoses, biopsy may be indicated to assess disease progression and response to therapy.[219]

Because drug-induced hepatotoxicity may be reversible on drug withdrawal, aggressive support for this cause of hepatic failure is indicated. Hepatitis B can be treated with the antiretrovirals lamivudine in combination with tenofovir or entecovir.[210] Recent advances in hepatitis C therapies demonstrate a greater sustained virologic response and in adult patients coinfected with HIV, and HCV should be treated with ribavirin, interferon, and sofosbuvir (an oral direct-acting antiviral that inhibits HCV polymerase).[210,229,230] In most cases HAART is suspended during hepatitis C therapy.[210,228] Liver transplantation can be successful with proper patient selection.[231]

Hematologic Complications

Hematologic abnormalities are common in patients with HIV/AIDS. Isolated thrombocytopenia is likely mediated by antiplatelet antibodies and should prompt HIV testing.[232-234] As with other forms of antibody-mediated thrombocytopenia, this may respond to immunoglobulin, steroids, or subtotal splenectomy.[233,235] Neutropenia may be antibody mediated, drug related, or secondary to sepsis. Granulocyte colony growth factors have reduced the incidence of sepsis in this setting.[236]

Anemia occurs in 20% to 73% of HIV-infected children and is an independent predictor of death from AIDS.[237-239] Most HIV-infected patients have normal erythrocyte size and shape but inadequate reticulocytosis. Iron deficiency, possibly related to malabsorption, accounts for 10% to 45% of anemia in HIV-infected children. Nutritional deficiencies of folate and vitamin B_{12} may also contribute to anemia. Many medications that are given to patients with AIDS cause anemia, including ZDV, acyclovir, TMP-SMX, and pentamidine. Anemia of chronic disease, mediated by inflammatory cytokines, likely accounts for additional cases. Rarely, antierythrocyte and antierythropoietin antibodies have been reported in patients with AIDS.[240] Pediatric patients with AIDS who have renal failure may lack erythropoietin.

Malignancies

Malignancies account for 2% of AIDS-defining illnesses in pediatric patients and are those typically associated with chronic viral infections.[241] In a cohort study of perinatally HIV-infected children, the cancer rate was nearly four times higher in children treated with HAART for less than 2 years when compared with those treated for more than 2 years.[242] The rates of childhood malignancy were compared between this cohort and the Surveillance, Epidemiology and End Result (SEER) Cancer Statistics Review. The higher rate in perinatally HIV-infected children was related to lymphomas. The development of cancer was three times more likely in those with low $CD4^+$ T-cell counts. EBV DNA has been identified in most CNS lymphomas, soft tissue leiomyosarcomas or rhabdomyosarcomas, and polyclonal, polymorphic B-cell lymphoproliferative disorder similar to that seen in transplant patients receiving immunosuppression. In addition, infection with human herpes virus type 8 (HHV-8) is associated with body cavity–based lymphoma and Kaposi sarcoma. Human papillomavirus is associated with invasive cervical cancer. Hepatitis B infection is associated with the development of hepatocellular carcinoma.[210]

Neurologic Complications

CNS involvement defined as seizure disorders, cerebral vascular accidents, CNS lymphoma, and aseptic meningitis occurs in 20% to 60% of HIV-infected children.[243] In this situation, treatable conditions must be ruled out before the diagnosis of AIDS encephalopathy can be made. Evaluation of these patients generally requires a series of biochemical and radiologic tests. Imaging studies such as CT and MRI can reveal

mass-occupying lesions such as intracranial hemorrhage, malignancies, or calcifications consistent with infection.[244,245] Lumbar puncture is necessary to rule out infection, and cerebral spinal fluid should be routinely cultured and investigated for specific pathogens via culture, direct antigen detection, and nucleic acid detection using PCR.[246,247]

HIV Encephalopathy

Primary HIV infection of the CNS probably occurs in 4% of HIV-infected children by the age of 12 months.[244] This entity is termed *HIV encephalopathy* and can generally be divided into two types: static with developmental delay or progressive similar to AIDS dementia in adults with progressive decline in neurologic functioning.[248-250] Direct HIV infection of the macrophages and microglia of the CNS is thought to cause release of inflammatory neurotoxins such as TNF or platelet-activating factor. Pathologically gliosis, microglial nodules, demyelination, and multinucleate giant cells are seen. Spinal cord examination similarly shows degeneration of corticospinal tracts, which clinically present as spastic diplegia. Vacuolar myelopathy involving the lateral and posterior columns, which presents as progressive muscle wasting and sensory loss, has also been observed in children.[243,251]

Diffuse atrophy is noted on CT, and bifrontal white matter abnormalities are commonly seen on MRI.[244,245,252,253] More severe cases of periventricular and centrum semiovale hypodense areas may occur. One-third of infected children may show calcifications of the basal ganglia. Calcifications observed before age 10 months are more likely due to an infection other than HIV, such as toxoplasmosis or CMV.[253]

AIDS encephalopathy is a diagnosis of exclusion. Other pathogens must be ruled out. Therefore evaluation includes imaging of the brain by CT or MRI and blood and CSF studies in search of specific pathogens such as *Cryptococcus,* mycobacterium, CMV, HSV, varicella-zoster virus, and *Treponema pallidum*. If no alternative pathogen is identified, then therapy is directed at reducing the HIV RNA viral load.[254]

Cerebrovascular Disease

Vascular complications involving the CNS in HIV-infected patients are many.[255] A cerebral vasculopathy was reported to occur in 25% of patients who underwent an autopsy. Although infarctions were first thought to be a consequence of direct HIV injury to the vascular endothelium, others now argue that the vascular injury results from other infections.[256,257] Cerebral vasculitis has been reported in CMV, HSV, neurosyphilis, and other infections of the CNS, even when they occur in non–HIV-infected patients. A hypercoagulable state associated with elevated levels of anticardiolipin antibody and antiphospholipid antibody, decreased levels of protein S, and a clinical condition similar to thrombotic thrombocytopenic purpura has also been described in association with HIV infection.[258] Although stroke is common in patients with AIDS, intracranial hemorrhage is relatively rare. Autoimmune-mediated thrombocytopenia, diffuse intravascular coagulation, and CMV infection have been reported to lead to intracranial hemorrhage in patients with AIDS.[243,255,259,260]

Central Nervous System Malignancy

High-grade B-cell lymphoma is found in 4% of HIV-infected children and is the most common mass lesion found in the CNS of children with AIDS.[242,243] It generally presents between ages 5 and 10 years. Lymphoma can be distinguished from toxoplasmosis by increased uptake of tracer on single photon emission computed tomography (SPECT) or positron emission tomography (PET) imaging. It most frequently arises in periventricular white matter and is associated with EBV infection. Metastatic lymphoma can also occur.

Infections of CNS

CNS infection by usual and opportunistic organisms in childhood AIDS accounts for only 13% of neurologic complications.[261-263] Primary CNS infections in HIV-infected children are caused by the usual etiologic bacterial organisms and *M. tuberculosis*. The usual presenting signs and symptoms are seen. Opportunistic infections such as CMV and aspergillosis are frequently observed at autopsy and generally result from disseminated disease.[261,263] Reactivated infections such as toxoplasmosis, herpes zoster, and progressive multifocal leukoencephalopathy caused by Jacob-Creutzfeldt virus infection also occur but are rare when compared with those in the adult population.[243,263,264]

The protozoal infection toxoplasmic encephalitis occurs in 30% of adult patients with AIDS but is generally seen in only older children. The incidence of maternal-fetal transmission does not appear to be affected by maternal HIV infection. Combination therapy with sulfadiazine and pyrimethamine is generally effective if initiated early. Clindamycin is an appropriate alternative in patients with sulfa allergy.[265] Corticosteroids are sometimes used in addition to first-line therapy to reduce edema. Relapse is common after treatment is stopped, and maintenance therapy is necessary. Primary prophylaxis is offered to adults with serologic findings that are positive for toxoplasma and a CD4 count of less than 200.

Progressive multifocal leukoencephalopathy presents with ataxia, aphasia, weakness, and lethargy.[261,266] CT may be relatively unremarkable with one or two nonenhancing hypodense areas of demyelination generally in subcortical white matter. MRI is more sensitive than CT for detection of these lesions. The lack of inflammatory finding is believed due to the severity of immune suppression. Presumptive diagnosis can be confirmed by stereotactic biopsy and identification of virus by DNA probes. The only treatment for this condition is HAART in the hopes that the immune system will be reconstituted; however, an inflammatory response during immune reconstitution may cause clinical deterioration and seizures.[267] Death is typically secondary to apnea, and although recovery is possible, residual deficits are likely.

Although not considered a reactivated infection, cryptococcal meningitis is typically seen in older children.[243,263] *Cryptococcus* spreads via the bloodstream to the CNS. Classic presentation includes fever, headache, and preceding alterations in mental status. Focal signs and meningeal signs are minimal. CSF counts may be normal, although intracranial pressure (ICP) is typically elevated. CT findings are nonspecific.

Treatment of coma in the HIV-positive patient is directed at the underlying cause. Supportive care follows the principles of therapy for all comatose patients, including airway protection, control of ICP where appropriate, and nutritional support.

Specific therapy for the underlying condition must be applied. In situations in which no explanation for an acute neurologic deterioration is readily available, it is appropriate to initiate antiviral therapy with ganciclovir, acyclovir, or both and await clinical improvement. This approach is based on evidence that CMV coinfection may be responsible for neurologic deterioration.[263] Some improvement has been reported in patients with HIV encephalopathy who were treated with ZDV or ganciclovir therapy, but the waxing and waning nature of the condition even without therapy makes any intervention difficult to evaluate.

Occupational HIV Exposure

Serious exposure to HIV in the health care setting is most likely to occur in the emergency department or ICU. The risk of exposure is 0.3% after a percutaneous exposure and 0.09% after blood or body fluid contact with nonintact skin or mucous membrane. Postexposure prophylaxis should be offered to all persons who have sustained a mucosal or parental exposure to HIV from a known infected source within 72 hours.[268] Postexposure prophylaxis regimen should consist of the US Public Health Service preferred regimen: Raltegravir (RAL) plus Truvada (TDF/FTC), although a high-risk exposure may warrant a third drug.[268] Women who receive postexposure prophylaxis should be offered emergency contraception to prevent pregnancy.[268] Repeat HIV antigen testing should be done 3 months after completion of the postexposure prophylaxis regimen.[268]

Summary

A critically ill child with a life-threatening infection or trauma should be presumed to be immunodeficient. The approach to such patients requires selective surveillance and a low threshold for empiric therapy. Through experience, patterns of infections characteristic of specific immunodeficient states can be recognized, but the unusual presentation is always possible. In the future, immune stimulants may also be part of the physician's armamentarium, in addition to antimicrobial therapy.

CHAPTER 105

Immune Balance in Critical Illness

SIRS, CARS, and Immunoparalysis

Mark W. Hall

PEARLS

- The inflammatory response to critical illness is highly dynamic over time and includes both proinflammatory and antiinflammatory features.
- These features constitute the systemic inflammatory response syndrome (SIRS) and compensatory antiinflammatory response syndrome (CARS).
- This balance is modulated by elements of both innate and adaptive immunity.
- The SIRS and CARS responses can temporally coexist, and their relative magnitudes are related to outcomes from critical illness.
- High plasma levels of interleukin (IL)-6 represent the marker of the SIRS response that is most strongly associated with adverse outcomes, though IL-8 levels may also be predictive.
- Quantitation of the CARS response can require specific testing, including measurement of plasma IL-10 levels, monocyte HLA-DR expression, quantitation of cytokine production capacity via ex vivo stimulation studies, and measures of lymphocyte apoptosis.
- Persistent and/or severe elevation in plasma IL-10 levels, reduction in monocyte HLA-DR expression, reduction in ex vivo lipopolysaccharide-induced tumor necrosis factor (TNF)-α production capacity, and lymphopenia have repeatedly shown association with increased risk for secondary infection and death across multiple forms of critical illness.
- These features are consistent with the phenomenon of immunoparalysis.
- Human in vivo evidence suggests that treatment with therapies such as granulocyte-macrophage colony-stimulating factor (GM-CSF) and interferon (IFN)-γ can reverse critical illness-induced innate immune suppression with the potential for benefit in terms of clinical outcomes.
- Evidence from in vivo animal studies suggests that treatment with adaptive-targeted therapies such as anti–PD-1 antibodies and IL-7 can reduce sepsis-

related mortality.

Introduction

From sepsis to trauma to cardiopulmonary bypass, critical illness is frequently characterized by derangements in the inflammatory response. Familiar to most are the canonical signs and symptoms of an exaggerated proinflammatory response including fever, capillary leak, and malperfusion. Less easily appreciated are the results of the inflammatory response's counterregulatory system. Like most biological processes, the inflammatory response includes mechanisms to downregulate its own activity. This compensatory response is, when prolonged and severe, increasingly recognized to be associated with increased risks of secondary infection and death from critical illness. These responses can affect the innate and adaptive arms of the immune system and can be quantified in the laboratory. This chapter focuses on the proinflammatory and antiinflammatory responses across innate and adaptive immunity, highlighting preclinical and clinical data that support the restoration of immunologic balance as an important goal in management of the critically ill patient.

Innate and Adaptive Immunity

Although details of innate and adaptive immune cell function can be found in Chapters 101 and 102, a brief review of the cast of characters that comprise the cellular and soluble elements of the inflammatory response are provided here. A limited list of these elements is presented in Table 105.1. There is considerable crosstalk between arms of the immune system, but it is useful to consider the innate and adaptive immune systems in turn.

TABLE 105.1

Selected Elements of Innate and Adaptive Immune Systems

Innate	
Cells	Neutrophils, monocytes, tissue macrophages, dendritic cells, natural killer cells
Functions	Phagocytosis, intracellular killing, antigen presentation, cytokine production
Receptors	Toll-like receptors, NOD receptors, Fc receptors, complement receptors
Cytokines/Chemokines Produced	
Proinflammatory	TNF-α, IL-1β, IL-8, MCP-1, IL-18
Antiinflammatory	IL-10, sTNFr, IL-1ra
Pleiotropic	IL-6
Adaptive	
Cells	T lymphocytes (helper T cells, cytotoxic T cells, regulatory T cells); B lymphocytes (plasma cells)
Functions	Cytokine production, cytotoxicity, antibody production, memory
Receptors	T-cell receptor, B-cell receptor
Cytokines/Chemokines Produced	
Proinflammatory	IFN-γ, IL-2, IL-17, GM-CSF, RANTES
Antiinflammatory	IL-10, TGF-β
Pleiotropic	IL-6

GM-CSF, granulocyte-macrophage colony-stimulating factor; *IFN*, interferon; *IL*, interleukin; *IL-1ra*, interleukin-1 receptor antagonist; *MCP*, monocyte chemotactic protein; *NOD*, nucleotide-binding oligomerization domain; *sTNFr*, soluble TNF receptor; *TNF*, tumor necrosis factor; *RANTES*, regulated on activation, normal T cell expressed and secreted; *TGF*, transforming growth factor.

Innate Immunity

Cells of the innate immune system include neutrophils, monocytes (and their descendants, tissue macrophages), dendritic cells, and natural killer cells. These cells, to varying degrees, carry out functions including the recognition of pathogens, phagocytosis of these pathogens, intracellular killing, and presentation of digested antigens on cell surface molecules to facilitate activation of lymphocytes. In addition, innate immune cells elaborate cytokines and chemokines that modulate the local environment and/or recruit other immune cells to the area of infection or injury.

Innate immune cells are typically the first cellular elements to become activated in the face of an inflammatory stimulus. This is by virtue of their constitutive expression of cell surface receptors for pathogen-associated molecular patterns (PAMPs) or endogenous danger-associated molecular patterns (DAMPs). These receptors can be activated by broad classes of ligands, an example of which is Toll-like receptor (TLR)-4, which is a key part of the PAMP receptor for lipopolysaccharide (LPS). Thus LPS should result in robust activation of innate immune cells upon the cells' first exposure without requiring antigen presentation or immunologic memory. This vigorous and prompt response is responsible for the central role innate immune cells are thought to play in the early and fulminant presentation of acute inflammatory conditions such as sepsis.

Adaptive Immunity

Lymphocytes comprise the adaptive arm of the immune system. Most lymphocytes can be classified as T or B cells, with T cells being responsible for cytokine production (in the case of CD4+ cells) and cytotoxicity (in the case of CD8+ cells). B cells, once activated, differentiate into plasma cells, which are responsible for antibody production. Lymphocytes typically require the presentation of antigenic peptides by activated members of the innate immune system in order to become activated, with the notable exception of superantigens, which can directly activate lymphocytes. T- and B-cell responses are generally highly antigen specific as the result of gene rearrangement within T- and B-cell receptors. Accordingly, only a small percentage of naïve lymphocytes are capable of responding to a given antigen. Lastly, once activated, a lymphocyte must clonally expand to mount a maximal immune response. Repeat exposure to an antigen, however, results in faster propagation of the immune response as the result of memory cells, which can persist for decades. The combination of the relative rarity of potentially responsive lymphocytes, the need for antigen presentation, and the potential need for clonal expansion explains the more subacute role that lymphocytes are thought to play in the perpetuation and modulation of the immune response to critical illness.

Proinflammatory and Antiinflammatory Responses

SIRS in Critical Illness

The elaboration of proinflammatory cytokines, including tumor necrosis factor (TNF)-α and interleukin (IL)-1β, and chemokines, such as IL-8, occurs rapidly

following activation of most innate immune cells. These cytokines act to produce elevated temperature (fever), vasodilation, and increased capillary permeability. Chemokines serve to promote recruitment of other immune cells to the area along a concentration gradient. These effects are beneficial when confined to a localized area of infection, allowing for increased delivery of leukocytes to these areas and enhanced killing of pathogens. When these effects become systemic, however, they become pathologic, leading to intravascular volume depletion, organ malperfusion, acidosis, organ failure, and death. Regardless of whether the insult prompting this activation is infectious (eg, sepsis) or noninfectious (eg, trauma, cardiopulmonary bypass, pancreatitis), the magnitude of the inflammatory response is frequently associated with adverse clinical outcomes.

Innate proinflammatory cytokines like TNF-α and IL-1β, however, peak early and have relatively short half-lives in the plasma. Often by the time a patient comes to medical attention following an acute proinflammatory insult, the plasma levels of these cytokines are waning. Interleukin-6 is made by multiple cell types including immune and nonimmune cells in response to stress and/or proinflammatory cytokines. Plasma IL-6 levels therefore remain elevated for far longer than those of TNF-α or IL-1β following the onset of a proinflammatory stimulus. In fact, numerous investigators have demonstrated that elevated plasma IL-6 levels predict mortality from forms of critical illness including sepsis and trauma in adults and children.[1-4] It is important to understand, however, that IL-6 is itself a pleiotropic cytokine. While it is a potent inducer of the hepatic acute phase response, IL-6 also has antiinflammatory properties including promoting production of glucocorticoids and antiinflammatory cytokines.[5] Interleukin-8 is a potent neutrophil chemokine whose levels in plasma can also be persistently elevated following an inflammatory insult. Low systemic IL-8 levels have been shown to predict favorable outcomes from pediatric septic shock,[6] while elevated IL-8 levels have been associated with increased mortality from pediatric trauma.[7]

The use of plasma biomarkers like IL-6 and IL-8 has the potential to identify high- (or low-) risk subjects for inclusion in clinical trials in the ICU. For example, in one of the few positive phase III clinical trials of anticytokine therapy in adult patients with severe sepsis, anti-TNF antibody fragment therapy was associated with reduced mortality in subjects with plasma IL-6 levels greater than 1000 pg/mL.[8] Given the complexity and redundancy of the proinflammatory cascade, however, it is possible that a combinatorial approach may be superior to single biomarkers in predicting outcomes. Wong et al. have repeatedly demonstrated high sensitivity and specificity in predicting pediatric sepsis mortality using a panel of biomarkers including IL-8, C-C chemokine ligand 3, heat shock protein 70, granzyme B, and matrix metalloproteinase-8.[9] It remains unclear whether specific plasma biomarkers such as these represent potential direct mediators of harm versus indirect measures of the proinflammatory response. The relationship between the magnitude of this response and clinical outcomes from critical illness, however, appears to be consistent.

CARS in Critical Illness

Within hours of activation of the proinflammatory response, immune cells begin elaborating counterregulatory antiinflammatory cytokines. These include molecules such as soluble TNF receptor (sTNFr) and IL-1 receptor antagonist (IL-1ra), which

impair the functionality of the proinflammatory cytokines. In addition, mediators such as IL-10 and transforming growth factor (TGF)-β are produced. They directly inhibit proinflammatory cells and/or repolarize them to an antiinflammatory/suppressed phenotype. Much as elevated plasma levels of proinflammatory cytokines are associated with adverse outcomes from critical illness, a similar relationship exists between antiinflammatory cytokine levels and clinical outcomes. High IL-10 levels have been associated with increased risks for secondary infection and/or mortality in the settings of adult and pediatric sepsis,[2,10,11] adult and pediatric trauma,[12,13] and pediatric cardiopulmonary bypass.[14]

Immune cell death represents another important counterregulatory response. Neutrophils typically die on release of their cargo of lytic enzymes and free radicals. In addition, lymphocyte apoptosis has repeatedly been shown to occur in the setting of adult and pediatric sepsis.[15,16] Phagocytosis of lymphocyte apoptotic bodies has also been shown to induce profound hyporesponsiveness of innate immune cells, demonstrating another example of innate and adaptive immune cell crosstalk.[17]

In addition to plasma cytokine levels and cell numbers, innate immune cell function has repeatedly been shown to be abnormal in many patients following the onset of critical illness. Human leukocyte antigen (HLA)-DR is a class II major histocompatibility complex (MHC) molecule that is present on the surface of antigen-presenting cells. These molecules display digested peptides on the innate immune cell's surface for presentation to adaptive immune cells. Monocyte HLA-DR expression is known to be reduced in the setting of sepsis, likely due to internalization of HLA-DR in subsurface vesicles.[18] The phenomenon of reduced monocyte HLA-DR expression has been demonstrated in adults and children in the aftermath of conditions as varied as trauma, cardiopulmonary bypass, multiple organ failure, and pancreatitis.[19-23]

Besides antigen presentation, the capacity of innate immune cells to respond to a new challenge has also been shown to be an important part of the CARS response. Specifically, the ability of blood samples to produce TNF-α when stimulated ex vivo with LPS has been shown to be reduced in many patients with critical illness. Ex vivo LPS-induced cytokine production capacity should be high in the healthy, immunocompetent state with innate immune cells (notably monocytes) producing the majority of the measured TNF-α. Downregulation of innate immune cell responsiveness can be marked and persistent in critically ill patients. This may seem counterintuitive given the proinflammatory nature of many clinical phenotypes seen in the ICU. It should be remembered, however, that many tissues produce proinflammatory mediators in the setting of stress. It is therefore likely that many of the systemic proinflammatory cytokines present beyond the first few hours of critical illness originate from injured tissues rather than from circulating leukocytes. Reductions in monocyte HLA-DR expression and/or ex vivo LPS-induced TNF-α production capacity that are severe and persistent following the onset of critical illness have been collectively termed "immunoparalysis."[24]

Lastly, specific cell types may play a role in the development and/or perpetuation of the immunoparalyzed phenotype. Work in critically ill adults has, for example, shown that the highly immunosuppressive regulatory T cell (T_{reg}), characterized by $CD4^+CD25^+FoxP3^+CD127^{lo}$ phenotype, can predominate in the subacute phase of sepsis.[25] These T_{regs} are known to produce large quantities of IL-10 and TGF-β and are felt to be resistant to the wave of lymphocyte apoptosis that occurs in sepsis.

Recent evidence also points to the elaboration of myeloid-derived suppressor cells (MDSC) from the bone marrow of critically ill patients.[26] These MDSC have the potential to produce high levels of antiinflammatory cytokines and facilitate T-cell suppression, though their role in critical illness-induced immune suppression is unclear.

Temporal Aspects of the SIRS/CARS Response

The classical view of the SIRS/CARS response involved the presence of two temporally distinct phases of illness in which the proinflammatory phase of SIRS was followed, over hours or days, by the antiinflammatory CARS phase. It is now appreciated that these two responses can and do coexist in the critically ill patient (Fig. 105.1). This is evidenced by the frequent occurrence of "cytokine storm" in which both proinflammatory and antiinflammatory mediators are elevated in the plasma simultaneously.[1,27] Gene expression studies, using mRNA from circulating leukocytes, have demonstrated upregulation of innate immune signaling pathways and downregulation of adaptive immune pathways in the early phases of sepsis and trauma.[28-30] Studies of functional measures of immunity (eg, monocyte HLA-DR expression, ex vivo LPS-induced TNF-α production capacity, and phytohemagglutin [PHA]-induced cytokine production capacity) suggest that leukocyte function can be reduced in both arms of the immune system with a day or two following critical illness onset.[13,31] As noted earlier, the initial peak of the leukocyte inflammatory response may have occurred before the patient is admitted to the ICU. Similarly, the CARS response may be well established by the time of ICU admission, despite persistently high levels of circulating proinflammatory mediators in the aftermath that follows the onset of critical illness.

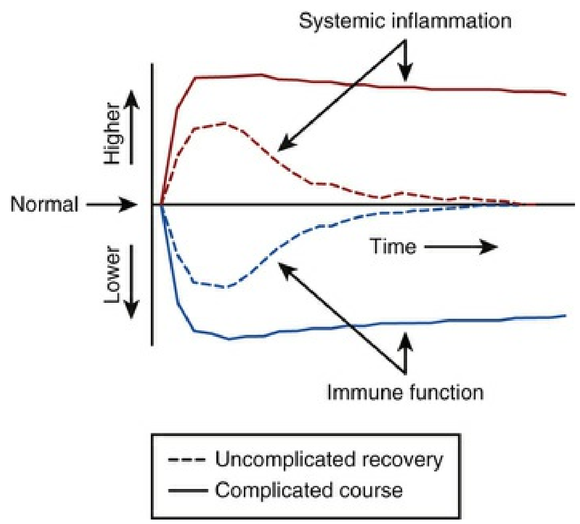

FIG. 105.1 Temporal aspects of the systemic inflammatory response syndrome (SIRS)/compensatory antiinflammatory response syndrome (CARS) response. After the onset of critical illness, there is typically a surge in systemic inflammation associated with the SIRS response *(red lines)*. A compensatory downregulation of immune cell function often occurs concomitant with this *(blue lines)*. Complicated outcomes (eg, secondary infection, death) are frequently associated with persistent elevations in systemic inflammation and persistently suppressed immune

function *(solid lines)*. Uncomplicated recovery is more often characterized by return to immunologic homeostasis *(dashed lines)*.

CARS and Clinical Outcomes

Not only is the state of immune suppression that characterizes the CARS response quantifiable, its severity is associated with adverse clinical outcomes. Severe reduction in monocyte HLA-DR expression has long been associated with secondary infection and mortality risk in adults with trauma and sepsis.[19,21] It has also been shown to carry these same associations in pediatric multiple organ dysfunction syndrome (MODS) and cardiopulmonary bypass.[20,22] Early work in this field suggested increased risks for adverse outcomes if less than 30% of monocytes strongly express HLA-DR by flow cytometry. More recent studies have used testing that is capable of quantitating the number of HLA-DR molecules per cell. Using this approach, investigators have identified a threshold of fewer than 8000 HLA-DR molecules per monocyte in defining the immunoparalyzed phenotype.[32] It is not clear if one method is superior to the other in predicting outcomes. Similarly, the ideal time frame for measuring HLA-DR expression is unclear. Some investigators have found that reduced HLA-DR expression correlates with adverse outcomes only after the first few days of illness, while others have shown associations within the first 48 hours.

Reduced whole blood ex vivo LPS-induced TNF-α production capacity has been similarly associated with adverse outcomes from critical illness including trauma and sepsis in adults[33,34] and MODS,[20] viral infections,[27,35] cardiopulmonary bypass,[14,36] and trauma[13] in children. Although distinct thresholds of TNF-α production capacity are dependent on the stimulation techniques that are used, standardized protocols that have successfully predicted outcomes in single-center and multicenter settings exist. It is unclear whether monocyte HLA-DR expression or ex vivo LPS-induced TNF-α production capacity is better for defining the innate immune system's CARS response in critical illness or if the measurement of both markers is required.

Acquired adaptive immune suppression is also a risk factor for adverse ICU outcomes. Severe lymphopenia and lymphocyte apoptosis in lymphoid organs have been shown to be associated with secondary infection and mortality risk in critically ill adults and children.[16,37] In an extension of earlier genomic work, Wong et al. demonstrated the ability to use patterns of leukocyte mRNA expression, focusing primarily on suppression of adaptive immunity and glucocorticoid receptor signaling genes, to predict mortality in derivation and validation cohorts (Fig. 105.2).[38] Lastly, impaired T-cell cytokine production capacity upon ex vivo stimulation with PHA, as early as 1 to 2 days after onset of illness, has been shown to be associated with infectious complications of pediatric septic shock.[31]

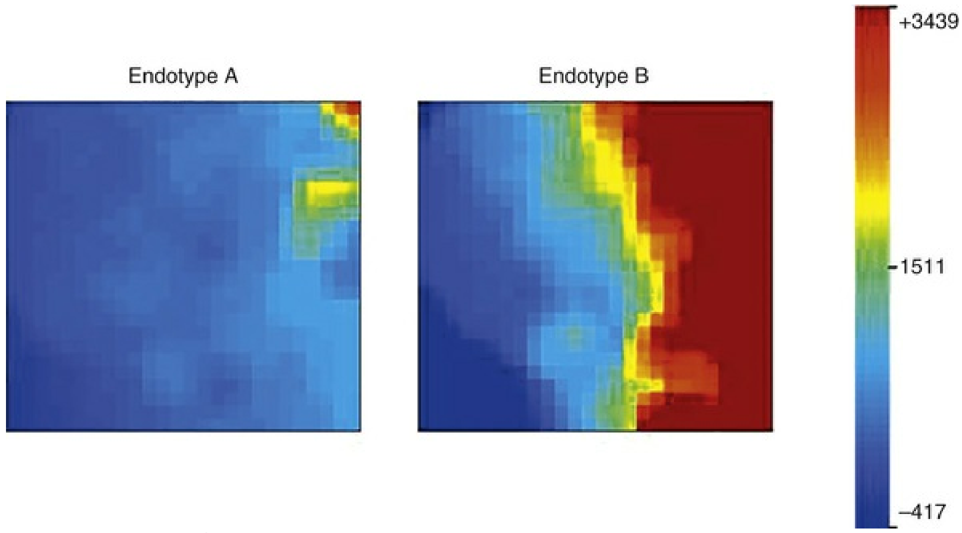

FIG. 105.2 Composite leukocyte gene expression in pediatric septic shock. Patients can be subclassified into endotypes on the basis of expression of 100 genes that regulate the adaptive immune response and glucocorticoid receptor signaling in leukocytes. The blue color represents decreased gene expression while the red color represents increased expression. Those falling in endotype A, with much greater downregulation of gene expression, demonstrated significantly greater mortality compared with endotype B in multiple large cohorts of septic children. (Images courtesy Dr. Hector Wong.)

In sum, there is a robust and growing body of literature suggesting that critical illness–associated immune suppression represents a major, yet often occult, risk factor for adverse outcomes across the spectrum of critical illness in adults and children. Because this phenomenon has been seen in both innate and adaptive immune cells, it stands to reason that both arms of the immune system may be targets for therapies aimed at restoring immune function.

Immune Modulation in Pediatric ICU

The intentional modulation of the inflammatory response is nothing new to the field of critical care medicine. A myriad of adult studies were published in the 1990s targeting the removal of selected proinflammatory mediators (eg, LPS, TNF-α, IL-1β) using monoclonal antibody therapy[39] (reviewed in). Phase III clinical trials of these agents were nearly universally unsuccessful in reducing sepsis mortality. Trials of potently immunosuppressive glucocorticoids such as methylprednisolone or dexamethasone, given with the intent of abrogating the proinflammatory response, similarly failed to improve sepsis outcomes in adults.[40] The use of methylprednisolone in the setting of acute respiratory distress syndrome (ARDS) has met with more mixed results, with recent evidence suggesting that early use may improve survival in adults.[41] Lastly, immunosuppressive treatments remain the mainstay for a host of acute and chronic inflammatory conditions that may result in critical illness including asthma, autoimmune disease, transplantation, and malignancy. Increasing appreciation of the phenomenon of immunoparalysis, however, has spurred the development of immunostimulatory therapies that have the potential to reverse critical illness–associated immune suppression.

Targeted Innate Immunostimulation

Two drugs that have been studied with the most rigor in the setting of critical illness–associated immune suppression are interferon (IFN)-γ and granulocyte-macrophage colony-stimulating factor (GM-CSF). IFN-γ is a proinflammatory cytokine made by T-helper 1 lymphocytes and is available for experimental human use. Systemic IFN-γ was used in a small series of septic adults with immunoparalysis, and its use was associated with normalization of monocyte HLA-DR expression and ex vivo LPS-induced TNF-α production capacity.[42] In addition, aerosolized IFN-γ has been shown to restore HLA-DR expression on alveolar macrophages and reduce ventilator-associated pneumonia risk in adult trauma patients with immunoparalysis.[43]

GM-CSF is a cytokine made by a number of different cell types, and it serves to promote the generation of new cells of the granulocyte and monocyte lineages from the bone marrow. In addition, GM-CSF is known to restore the activity of immunoparalyzed monocytes in vitro.[13] GM-CSF is FDA approved for use in children and adults for reconstitution of bone marrow following hematopoetic stem cell transplantation and/or chemotherapy. Like IFN-γ, GM-CSF has been shown to restore monocyte HLA-DR expression and TNF-α production capacity in an uncontrolled series of immunoparalyzed, septic adults.[44] It has also been evaluated in randomized controlled trials in critically ill adults and children, the results of which have suggested faster resolution of innate immune suppression, when present, and/or decreased infection risk compared with placebo. A summary of clinical trials using immunostimulation for treatment of critical illness–associated immune suppression is presented in Table 105.2.[45-50]

TABLE 105.2

Summary of In Vivo Immunostimulation Studies in Critically Ill Adults and Children

Author	Year	Study Type	Number	Population	Drug	Results	Reference
Livingston et al.	1994	RCT	98	Adult trauma	IFN-γ	↑ Monocyte HLA-DR expression	45
Spagnoli et al.	1995	RCT	10	Adult trauma	GM-CSF	↑ Monocyte HLA-DR expression	46
Döcke et al.	1997	Case series	9	Adult sepsis with immunoparalysis	IFN-γ	↑ Monocyte HLA-DR expression and ex vivo LPS-induced TNF-α production capacity	42
Nakos et al.	2002	RCT	21	Adult trauma with immunoparalysis	IFN-γ (inhaled)	↑ Alveolar macrophage HLA-DR expression, reduced VAP risk	43
Nierhaus et al.	2003	Case series	9	Adult sepsis	GM-CSF	↑ Monocyte HLA-DR expression and ex vivo LPS-induced TNF-α production capacity	44
Rosenbloom et al.	2005	RCT	40	Adult sepsis	GM-CSF	↑ Innate immune function	47
Orozco et al.	2006	RCT	58	Adult sepsis	GM-CSF	Improved infection outcomes	48
Meisel et al.	2009	RCT	38	Adult sepsis with immunoparalysis	GM-CSF	↑ Monocyte HLA-DR expression and ex vivo LPS-induced TNF-α production capacity, improved organ function	49
Hall et al.	2011	RCT	14	Pediatric MODS with immunoparalysis	GM-CSF	↑ Ex vivo LPS-induced TNF-α production capacity, reduced nosocomial infection risk	20
Paine et al.	2012	RCT	130	Adult ARDS	GM-CSF	No change in ventilator-free days (no immune parameters measured)	50

ARDS, acute respiratory distress syndrome; *GM-CSF*, granulocyte-macrophage colony-stimulating factor;

IFN, interferon; *LPS*, lipopolysaccharide; *MODS*, multiple organ dysfunction syndrome; *RCT*, randomized controlled trial; *TNF*, tumor necrosis factor.

Targeted Adaptive Immunostimulation

There are fewer pharmacologic choices when trying to target lymphocyte stimulation in critically patients, as there are currently no known lineage-specific colony-stimulating factors that promote lymphocyte development and function. There are, however, other options for preserving or enhancing lymphocyte function. The cell surface molecule PD-1 is a negative costimulatory molecule that is present on lymphocytes. When bound by its ligands PD-L1 or PD-L2, expressed by antigen-presenting cells, it induces lymphocyte deactivation or apoptosis. The expression of both PD-1 and its ligands is upregulated in septic shock.[37,51] This represents a potential mechanism for sepsis-induced lymphopenia and lymphocyte suppression. Murine data suggest that blockade of PD-1 using anti–PD-1 antibodies can be protective in a two-hit model of cecal ligation and puncture (CLP) followed by airway infection.[52] Interleukin-7 is an endogenous cytokine that promotes lymphocyte development and survival. Recombinant IL-7 has been shown, also in mice, to similarly improve survival in two-hit CLP models.[53] Interestingly, it appears that combinatorial therapy with both anti–PD-1 and IL-7 in these models may have greater benefit than either agent alone.[54] Both anti–PD-1 and recombinant human IL-7 have potential applications as cancer therapeutics and may be available for clinical trials in critically ill humans in the near future.

Unintended Immunomodulation

In addition to the forms of intentional immunomodulation described earlier, it is important to understand that many therapies that are applied to critically ill patients have unintended effects on immune function (Table 105.3). From sedatives and analgesics to inotropes and diuretics, much of the ICU pharmacopeia is immunodulatory with most of these drugs having direct or indirect immunosuppressive effects. In addition, the transfusion of blood products, particularly stored red blood cells (RBCs), is thought to modulate immune function (see also Chapter 93). Although transfusion-related immunomodulation (TRIM) was once viewed as a proinflammatory syndrome, the broad implementation of prestorage leukoreduction of RBC units has reduced acute proinflammatory transfusion reactions.[55] Instead, increasing evidence points to an immunosuppressive effect of RBC transfusion, especially in the setting of prolonged pretransfusion storage.[56] Lastly, the use of extracorporeal life support devices causes leukocyte activation due to exposure to artificial tubing and membranes. It is unclear if these devices promote the immunoparalyzed phenotype in the subacute phase. Intriguingly, the use of adsorptive membranes designed to specifically deplete proinflammatory mediators such as complement, IL-6, and LPS may have the potential to improve innate immune function during sepsis, with improvements in monocyte HLA-DR expression seen in small clinical trials.[57]

TABLE 105.3

Immunomodulatory Properties of Commonly Used ICU Medications

Drug	Immune Effect	Mechanism
Catecholamines		
α-Agonists	↑	Direct and indirect potentiation of proinflammatory signaling
β-Agonists	↓	Direct and indirect potentiation of antiinflammatory signaling
Antibiotics		
β-Lactams	↓	Bone marrow suppression, ↓ cytokine production
Macrolides	↓	↓ Cytokine production
Insulin	↓	↓ Proinflammatory signaling
Furosemide	↓	↓ Cytokine production
Sedatives		
Benzodiazepines	↓	↑ Cortisol response, direct leukocyte inhibition
Barbiturates	↓	↓ Neutrophil function
Analgesics		
Opiates	↓	↓ Proinflammatory cytokine production, ↑ production of TGFβ, ↑ leukocyte apoptosis
NSAIDs	↓	↓ Cytokine production

NSAIDs, nonsteroidal antiinflammatory drugs; *TGF*, transforming growth factor.

Immune Monitoring in ICU

The current routine clinical practice in the United States for immune function monitoring in critically ill patients is limited to the measurement of complete blood counts and nonspecific markers of inflammation such as C-reactive protein (CRP) levels. While the clinical use of measures of immune function such as monocyte HLA-DR expression and ex vivo LPS-induced TNF-α production capacity is possible in Europe, these assays are currently limited to research use in the United States. It remains unclear if monocyte HLA-DR expression is best measured using the percent-positive or molecules-per-cell approach. As for quantitation of TNF-α production capacity, it has been shown that highly reproducible single-center and multicenter results can be obtained using a standardized approach to ex vivo stimulation. The lack of an industry-standard approach, however, makes the generalization of specific treatment thresholds difficult because the TNF-α response will vary from protocol to protocol depending on the type of LPS used and other experimental conditions. Additional consensus in the field is required in order to move this immune function testing to the clinical laboratory.

The reactivation of latent viruses represents an intriguing indirect measure of immune function that may have utility in the ICU. Recent evidence suggests that many patients with critical illness demonstrate PCR positivity for latent viruses in the bloodstream over time and that this viral reactivation is associated with increased mortality.[58] It is possible that this circulating viral DNA represents a sequela of critical illness–associated immune suppression and/or may mediate some of the adverse effects of such suppression. Additional research is necessary in this area.

Lastly, the host genome represents a potential target for immune-related testing. It has been known for many years that there is a familial predisposition to adverse outcomes from critical illness. Westendorp et al. demonstrated this nicely with an analysis of ex vivo LPS-induced cytokine production capacity in first-degree relatives of patients with meningococcemia.[59] Relatives of nonsurvivors could be identified by their production of low amounts of TNF-α and high amounts of the antiinflammatory cytokine IL-10 upon stimulation, suggesting that immunoparalysis may be a heritable trait. Unfortunately, no single polymorphism has been

consistently associated with clinically relevant derangements of the immune response in critical illness. Further complicating this analysis is the fact that epigenetic factors may influence the inflammatory response. Cornell et al. were able to identify a histone methylation pattern in the IL-10 promoter region, resulting in a “gene on” configuration in children with immunoparalysis following pediatric cardiopulmonary bypass.[36] The immune phenotype may, therefore, be influenced by fixed genetic factors, as well as potentially modifiable epigenetic factors over the course of critical illness.

Conclusion

The immune response during critical illness, once thought to be limited to a proinflammatory surge, is now known to be highly dynamic with proinflammatory and antiinflammatory forces at work. The balance between these forces determines the patient's ability to respond to new infectious challenges, heal injured tissues, and resolve systemic inflammation. It is increasingly apparent that failure to achieve immunologic homeostasis is associated with increased risks for adverse outcomes across the spectrum of adult and pediatric critical illness. It is similarly apparent that although antiinflammatory therapies are appropriate for some patients, immunostimulatory therapies may be indicated for others. The development of a personalized approach to the identification and management of an abnormal immune response is necessary in pediatric critical illness, involving standardized prospective functional testing. In addition, critically ill patients require a more comprehensive understanding of the multilayered interactions among the host, the pathogen, and treatment-related factors.

CHAPTER 106

Pediatric Rheumatic Disease

Diagnosis, Treatment, and Complications

Alexandra R. Aminoff, Carol A. Wallace

PEARLS

- Approximately 1 child in 250 has a rheumatic disease.
- A child may present to the ICU with a life-threatening manifestation of an undiagnosed rheumatic disease or with severe complications of a known rheumatic disorder.
- Suspicion for rheumatic disease should be high when children present with persistent fevers of unknown origin, multisystem involvement, joint involvement, or unexplained high inflammatory markers.
- Diagnosing rheumatic diseases is challenging as few clinical features are pathognomonic and few diagnostic tests are confirmatory. A thorough history and physical examination are essential.
- Infectious and oncologic processes may mimic rheumatic diseases and must be excluded.
- Serious complications of rheumatic diseases can affect any organ system, be life threatening, and include stroke, psychosis, pulmonary hemorrhage, renal failure, and prothrombotic states.
- Macrophage activation syndrome is a severe "cytokine storm" due to immune dysregulation in the setting of rheumatic diseases, infections, and malignancy. Its early recognition and aggressive treatment are essential, as it can lead to severe morbidity and death.
- High-dose corticosteroid therapy is frequently used at diagnosis and for severe disease flares to bring inflammation under control quickly. Corticosteroids are typically not sufficient to maintain long-term disease control and have many associated risks, so additional immunosuppressive therapy is employed to induce and maintain remission.
- Immunosuppressive therapy used to treat rheumatic diseases can lead to complications including infections, liver disease, renal disease, and cytopenias.

Adrenal insufficiency chronic corticosteroid use can occur if corticosteroids such treatment is stopped abruptly.

- Therapy for rheumatic disease may be initiated in the ICU and often includes high-dose corticosteroids, cyclophosphamide, anticytokine, and anticellular biological therapies; IV immunoglobulin; and plasmapheresis. Management may be challenging, given the complexities of the diseases, multiple organ systems involved, and potential complications of treatment.

Rheumatic diseases are caused by dysfunction of the immune system, resulting in autoimmunity due to loss of self-tolerance and abnormal inflammatory responses.[1] These diseases affect approximately 1 child in 250. Although largely an outpatient-based specialty, pediatric rheumatology encompasses a diverse set of diseases that can be difficult to diagnose and treat, with complications that can be life threatening. The number of children with rheumatic disease who require intensive care management is unknown, but early diagnosis and rapid treatment can significantly decrease morbidity and mortality.[2,3] Patients may present to the ICU with life-threatening manifestations of new-onset rheumatic disease, with severe complications of a known disorder, or with complications secondary to immunosuppressive therapy. This chapter provides an overview of the most common pediatric rheumatic diseases followed by a discussion of the conditions and complications most likely to be encountered in the ICU.

Rheumatic Diseases: Clinical Presentation, Diagnosis, and Treatment

Rheumatic diseases in children present in highly variable ways and are best diagnosed by a thorough history and physical examination. They should be considered in patients who present with unexplained fevers or constitutional symptoms, multisystem involvement, or unexplained systemic inflammation. Laboratory tests may be consistent with and confirm clinical suspicions but are often not diagnostic.

Juvenile Idiopathic Arthritis

Juvenile idiopathic arthritis (JIA) is the most common childhood rheumatic disease and can present in several different forms (Box 106.1).[4] Most children are managed as outpatients, but the disease and its complications occasionally require intensive care. The JIA category that most often requires ICU-level care is systemic-onset JIA (soJIA), which accounts for about 10% to 20% of children with JIA. It can present with severe multisystem disease including the life-threatening cytokine storm known as *macrophage activation syndrome* (MAS), discussed later in the chapter.

Box 106.1

Criteria for Juvenile Idiopathic Arthritis (JIA)

JIA is a disease of childhood onset characterized primarily by arthritis persisting for

at least 6 weeks with no known cause.

Systemic Arthritis

Arthritis with or preceded by daily fever of at least 2 weeks' duration, which is documented to be quotidian for at least 3 days, and accompanied by one or more of the following:

- Evanescent, nonfixed, erythematous rash
- Generalized lymph node enlargement
- Hepatomegaly or splenomegaly
- Serositis

Oligoarthritis or Polyarticular Arthritis

Arthritis affecting one to four joints during the first 6 months of disease. Two subcategories are recognized:

- Persistent oligoarthritis: Affects no more than four joints throughout the disease course
- Extended oligoarthritis: Affects a cumulative total of five joints or more after the first 6 months of disease

Polyarthritis (Rheumatoid Factor Negative)

Arthritis affecting five or more joints during the first 6 months of disease; tests for rheumatoid factor are negative.

Polyarthritis (Rheumatoid Factor Positive)

Arthritis affecting five or more joints during the first 6 months of disease associated with positive rheumatoid factor tests on two occasions at least 3 months apart.

Psoriatic Arthritis

Arthritis and psoriasis or arthritis and at least two of the following:

1. Dactylitis
2. Nail abnormalities (pitting or onycholysis)
3. Family history of psoriasis confirmed by a dermatologist in at least one first-degree relative

Enthesitis-Related Arthritis

Arthritis and enthesitis or arthritis or enthesitis with at least two of:

- Sacroiliac joint tenderness and/or inflammatory spinal pain
- Presence of HLA-B27

- Family history in at least one first- or second-degree relative of medically confirmed HLA-B27–associated disease

- Anterior uveitis that is usually associated with pain, redness, or photophobia

- Onset of arthritis in a boy after 8 years of age

Other Arthritis

Children with arthritis of unknown cause that persists for at least 6 weeks but that either:

- Do not fulfill criteria for any of the other categories, *or*

- Fulfill criteria for more than one of the other categories

HLA, human leukocyte antigen.

Adapted from Petty RE, Southwood TR, Manners P, et al. International League of Associations for Rheumatology classification of juvenile idiopathic arthritis: second revision. J Rheumatol. 2004;31:390-392.

Systemic-Onset Juvenile Idiopathic Arthritis Clinical Presentation

The classic features of soJIA include high-spiking fevers, evanescent rash, and arthritis.[5] The fevers (temperatures ≥39°C) typically occur in a spiking quotidian pattern—with return to normal temperature daily—for at least 2 weeks. The rash is typically a nonpruritic, salmon-colored, macular rash that can be subtle. It usually occurs with fever spikes and is rapidly migratory, often disappearing completely when the temperature normalizes. While a complete joint examination is essential, arthritis may not be a prominent feature early in disease. Other clinical features may include diffuse lymphadenopathy and hepatosplenomegaly. Malignancy and infectious processes must be excluded.

Cardiac involvement is uncommon in JIA (≈3%–9%) and typically presents as pericarditis with or without pericardial effusion.[6] It is most commonly seen in soJIA and rarely causes cardiac tamponade. Pulmonary complications may also occur—pleural involvement is most common, but parenchymal disease, such as interstitial lung disease or bronchiolitis obliterans, and pulmonary hypertension sometimes occur.[7,8] Lung complications are most typically seen in soJIA but rarely occur in rheumatoid factor-positive polyarticular JIA or secondary to drug toxicity (methotrexate).

Arthritis of the cervical spine can be seen in several of the JIA categories, causing decreased range of motion and instability. Synovial inflammation and bony erosions in the occipitoatlantoaxial joints can lead to C1-C2 instability and potential neurologic complications.[9] This has important implications in the ICU setting if hyperextension is attempted for intubation. In any patient with JIA with a history or findings of cervical spine disease, radiographic imaging with neck flexion/extension views should be obtained before attempted intubation. If abnormalities are identified, alternative airway management, such as fiberoptic visualization or tracheostomy, should be considered. Temporomandibular joint arthritis can cause a diminished mouth opening, which can also complicate airway management. Cricoarytenoid arthritis may present as sore throat with localized tenderness over

the joints or with stridor and airway obstruction due to limited vocal cord mobility.

Uveitis is a common complication in children with JIA, particularly children who are antinuclear antibody (ANA) positive. Uveitis is not typically associated with soJIA.

Laboratory Studies

Laboratory findings consistent with soJIA include anemia (with hemoglobin levels often between 6 and 8 g/dL); elevated white blood cell (WBC) counts, sometimes in the leukemoid range; and elevated platelet counts. Cytopenias should prompt consideration of MAS or malignancy. C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) are usually markedly elevated, although in the setting of MAS the ESR may fall due to declining fibrinogen levels. ANA, rheumatoid factor, and anticyclic citrullinated peptide (anti-CCP) antibodies are typically absent, unlike other forms of JIA.

Management

Children with active soJIA should be treated aggressively, typically with high-dose pulse IV methylprednisolone (30 mg/kg/day, maximum dose 1000 mg) administered over 1 hour for 3 consecutive days. Subsequent maintenance prednisone is given intravenously or by mouth at 1 to 2 mg/kg/day, divided twice a day until symptoms resolve. Corticosteroid-sparing agents, such as anakinra (an IL-1 receptor blocker), tocilizumab (an anti-IL-6 therapy), or cyclosporine (a calcineurin inhibitor), should be introduced ideally in consultation with a pediatric rheumatologist.[10] These agents are used to induce remission and maintain disease control as corticosteroids are weaned. The immediate complications of high-dose corticosteroid therapy include sodium and fluid retention, hypertension, gastritis, risk for infection, and hyperglycemia.[11] In many centers, corticosteroids are not being used at all, in favor of anti-IL-1 monotherapy.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a vasculitis due to autoantibodies forming immune complexes, which target a wide variety of organs resulting in multisystem disease. Immune dysregulation, genetic, environmental, and hormonal factors all contribute to the pathogenesis of this disease.[12] Girls, particularly in adolescence, are most likely to be affected; however, boys and young children can also develop SLE. The classification criteria (Box 106.2)[13,14] are helpful in making the diagnosis—if 4 of the 11 criteria are met, a diagnosis of SLE is highly likely. However, SLE presentation can be extremely variable—any organ system may be affected and the disease can be mild to life threatening. If the diagnosis is being considered, a thorough evaluation of all organ systems and serologic tests for SLE specific autoantibodies (discussed later) and other SLE markers is essential.

Box 106.2

1982 Revised Criteria for Classification of Systemic Lupus Erythematosus (SLE) With 1997 Revision

The proposed classification is based on 11 criteria. For the purpose of identifying patients in clinical studies, a person is defined as having SLE if any 4 or more of the 11 criteria are present, serially or simultaneously, during any interval of observation.

1. Malar rash: Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds

2. Discoid rash: Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions

3. Photosensitivity: Skin rash as a result of unusual reaction to sunlight, by patient history or physician observation

4. Oral ulcers: Oral or nasopharyngeal ulceration, usually painless, observed by physician

5. Arthritis: Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion

6. Serositis

a. Pleuritis: A convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion *or*

b. Pericarditis: Documented by electrocardiogram or rub or evidence of pericardial effusion

7. Renal disorder

a. Persistent proteinuria >0.5 g/day (or >3+ if quantitation not performed) *or*

b. Cellular casts (may be red cell, hemoglobin, granular, tubular, or mixed)

8. Neurologic disorder

a. Seizures in the absence of offending drugs or known metabolic derangements (eg, uremia, ketoacidosis, or electrolyte imbalance) *or*

b. Psychosis in the absence of offending drugs or known metabolic derangements (eg, uremia, ketoacidosis, or electrolyte imbalance)

9. Hematologic disorder

a. Hemolytic anemia with reticulocytosis *or*

b. Leukopenia <4000/uL total on two or more occasions *or*

c. Lymphopenia <1500/uL on two or more occasions *or*

d. Thrombocytopenia <100,000/uL in the absence of offending drugs

. Immunologic disorder

a. Anti-DNA: Antibody to native DNA in abnormal titer *or*

b. Anti-SM: Presence of antibody to Sm nuclear antigen *or*

c. Positive finding of antiphospholipid antibodies based on:

1. an abnormal serum level of immunoglobulin G or immunoglobulin M anticardiolipin antibodies *or*
2. a positive test result for lupus anticoagulant using a standard method *or*
3. a false-positive serologic test result for syphilis and confirmed by *Treponema pallidum* immobilization or fluorescent treponemal antibody absorption test

. An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with drug-induced lupus syndrome

Adapted from Tan EM, Cohen AS, Fries JF, et al. The 1982 revised criteria for the classification of systemic lupus erythematosus. Arthritis Rheum. 1982;25:1271-1277 and Hochberg MC. Updating the American College of Rheumatology revised criteria for the classification of systemic lupus erythematosus. Arthritis Rheum. 1997;40:1725.

Clinical Presentation

Mucocutaneous Manifestations

Malar rash, discoid rash, photosensitivity, oral ulcerations (especially over the hard palate), and nasal ulcerations are classic. However, almost any kind of rash, including bullous lesions, may be seen. Skin biopsy with immunofluorescence staining to demonstrate immune complex deposition can be helpful.

Musculoskeletal Manifestations

Arthritis is common, occurring in 80% of patients with SLE. A musculoskeletal examination should be performed to look for joint tenderness, contracture, or effusion. Myositis is less common but can also occur. Avascular necrosis can occur and may be due to the disease itself or to corticosteroids.

Pulmonary Manifestations

Pulmonary manifestations occur commonly.[15] Pleuritis is included in the classification criteria and may be severe, causing respiratory compromise. Pulmonary hemorrhage is one of the most serious complications and may be precipitated by vasculitis or infection. SLE should always be considered in a patient presenting with pulmonary hemorrhage. Pulmonary embolism may occur secondary to antiphospholipid (APL) antibodies or other hypercoagulable states such as nephrotic syndrome. Smaller and recurrent emboli may contribute to the development of pulmonary hypertension, another severe SLE complication. "Shrinking lung" syndrome, a severe restrictive lung disorder attributed to diaphragm dysfunction, is rare in pediatric SLE.

Cardiovascular Disease

Any layer of the heart including the pericardium, myocardium, and valves may become inflamed, leading to cardiovascular compromise. Libman-sacks endocarditis involves the development of sterile vegetations on the cardiac valves, most commonly the mitral valve. Vasculitis can affect any organ in the body including the gastrointestinal (GI) tract, skin, and brain, leading to thrombotic and hemorrhagic complications. Vasculitis in the coronary vessels increases the risk of myocardial infarction. Patients with SLE are at higher risk for premature cardiovascular disease, which may relate to chronic inflammation and side effects of long-term steroid use, such as hyperlipidemia and hypertension.

Renal Manifestations

Renal disease is estimated to occur in 50% to 80% of children with SLE and is often more severe than renal disease in adult patients.[16] Lupus nephritis can range from asymptomatic with an abnormal urinalysis to renal failure requiring dialysis, severe nephrotic syndrome, and malignant hypertension. Renal biopsies help to determine the severity, type, and extent of lupus nephritis, which has major implications for treatment.

Central Nervous System Disease

Seizures and psychosis are the CNS manifestations included in the SLE classification criteria, but the neuropsychiatric features of SLE are diverse and of variable severity. These features may be the initial presentation of SLE or occur at any point during the disease course, even when the disease is otherwise not active.[17] Thromboembolic events can occur in the setting of APL antibodies or vasculitis and result in CNS disease.

Hematologic Involvement

Cytopenias are common and are often a presenting feature of SLE. Antibody-

mediated cytopenias (such as Coombs-positive hemolytic anemia) are frequent, but other factors such as blood loss, bone marrow suppression, medications, or infection should also be considered. Prophylaxis against opportunistic infections may be necessary in patients with severe lymphopenia (<500/uL). A high white blood cell count in the setting of active lupus should prompt consideration of infection but can also be caused by neutrophil demargination from high-dose corticosteroid therapy.

Immune Dysfunction

Patients with SLE are immunosuppressed by the disease itself due to abnormal B- and T-cell function and low complement levels that impair opsonization of encapsulated organisms. The immunosuppressive agents used to control the disease may additionally impair the ability to fight infection. Patients with SLE are also at risk of developing MAS, discussed later.

Laboratory Studies

Although more than 95% of patients with SLE have a positive ANA test, this can occur in many other conditions including other rheumatic diseases, infection, malignancy, and healthy people. Unlike the ANA, anti–double-stranded DNA (dsDNA) antibodies are highly specific for SLE and are elevated in 80% to 90% of children with SLE at some point in the disease course. Anti-Smith (Sm) antibodies are also highly specific for SLE but are seen less commonly, in approximately 20% of pediatric patients.[18]

Antibodies to SSA, SSB, and ribonucleoprotein (RNP) occur in varying frequency. Complement levels (C3 and C4) are typically low in active disease, reflecting consumption in the setting of immune complex formation. Serial measurements of C3, C4, and anti-dsDNA are useful in monitoring disease activity.

Management

Patients with SLE often require ICU-level care and can be severely ill at diagnosis and with disease flares. Treatment is typically initiated with high-dose pulse IV methylprednisolone (30 mg/kg/day, maximum dose 1000 mg), administered over 1 hour for 3 consecutive days. Subsequent maintenance prednisone is given intravenously or by mouth at 1 to 2 mg/kg/day divided twice a day. Steroid-sparing agents such as cyclophosphamide and rituximab (an anti-CD20 antibody) are typically necessary in patients with significant CNS or renal involvement. For patients with less severe disease, mycophenolate mofetil (MMF) or azathioprine is typically used to induce remission. Renal failure and dialysis can affect drug metabolism and clearance; consultation with pediatric nephrology and pharmacy services may assist with proper dosing.

Neonatal Autoimmune Syndromes

Infants can develop antibody-mediated disease due to transmission of maternal antibodies in utero; mothers may or may not be symptomatic from these autoantibodies. Symptoms can present prenatally or up to 6 months of age and persist for 6 to 9 months until the maternal antibodies are cleared from the infant's circulation. Passage of maternal anti-SSA and anti-SSB antibodies can result in rash, transaminitis, cytopenias (typically thrombocytopenia), and heart block.[19] The heart

block can be severe and irreversible, requiring a pacemaker. Infants can also develop isolated autoimmune cytopenias due to maternal antibodies, such as antiplatelet antibodies causing neonatal thrombocytopenia. As the maternal antibody levels in the infant's circulation decline, the manifestations usually resolve; however, exchange transfusion has been used in severe cases.

Juvenile Dermatomyositis

Clinical Presentation

Juvenile dermatomyositis (JDM) is a vasculitis that primarily targets the skin and muscles. It is characterized by weakness and skin findings: rash over the eyelids (heliotrope rash), face (malar rash), neck and upper back (shawl sign), extensor surfaces of the joints in the hands, elbows, and knees (Gottron papules), and periungual telangiectasias.[20] The inflammation primarily affects striated muscle but can also involve smooth muscle. Typically proximal rather than distal muscle groups are affected, leading to profound shoulder and hip girdle muscle weakness. The muscles of the palate, pharynx, and upper third of the esophagus can also be involved, resulting in dysphagia, dysphonia, and risk of aspiration. In severe cases, weakness may lead to respiratory failure but this may not be apparent as weakness can mask typical signs of distress.

Vasculitis can also target the gastrointestinal (GI) tract and cause bleeding, necrosis, and perforation. Cardiac muscle can become inflamed, and rarely myocarditis and conduction defects have been reported. Interstitial lung disease occurs and may be difficult to detect early in disease. The kidneys are not typically targeted by vasculitis in JDM, but rhabdomyolysis with secondary renal impairment can rarely occur. As with many of the rheumatic diseases, severely ill patients with JDM can develop MAS. A more long-term complication of JDM is calcinosis, with calcium deposition in the skin, particularly around the joints. In severe cases, this can impair mobility. Malignancy is rarely associated with JDM as opposed to adult dermatomyositis.

Laboratory Studies

Laboratory studies are useful to support the diagnosis, monitor disease activity, and guide treatment. Serum levels of muscle enzymes, including creatine kinase, aspartate transaminase (AST), alanine transaminase (ALT), aldolase, and lactate dehydrogenase, are usually markedly elevated. Mild anemia may be present initially, but the WBC and platelet counts should be normal. Severe anemia, leukopenia, and/or thrombocytopenia should prompt consideration of MAS or investigation of other causes than JDM.

Imaging

The muscle edema and inflammation of JDM are best detected by MRI with short tau inversion recovery (STIR) sequence. MRI can also help to identify an appropriate site for biopsy in cases with diagnostic uncertainty. A barium swallow initially is important to identify esophageal dysmotility and the need for medication for acid reflux. For patients with dysphonia or dysphagia, a video fluoroscopic swallowing study (VFSS) can establish aspiration risk and whether alternative feeding methods

are necessary. Electrocardiogram (ECG), echocardiogram (ECHO), chest radiograph, chest computed tomography (CT), and pulmonary function tests help to establish the extent of cardiopulmonary involvement. Abdominal CT can be performed if GI involvement is suspected.

Management

An aggressive treatment approach is essential and typically includes high-dose IV corticosteroids, methotrexate, and IV immunoglobulin (IVIG). Treatment should be initiated immediately to prevent life-threatening complications, permanent muscle destruction, and long-term sequelae such as calcinosis. Other agents, such as cyclosporine, MMF, cyclophosphamide, and rituximab may be used in refractory or severe cases.[21] In cases complicated by GI vasculitis, medications administered orally may not be absorbed reliably and parenteral administration is preferred.

Scleroderma (Systemic Sclerosis)

Clinical Presentation

Scleroderma refers to a group of rare connective tissue diseases in which vascular changes and fibrosis lead to hardening of the skin and abnormalities of the internal organs, especially the lungs and GI tract. Diffuse systemic sclerosis is the most severe form of the disease, and features may include skin induration, Raynaud phenomenon (discussed later), digital tip ulceration, dysphagia, gastroesophageal reflux, hypertension, arthritis, neuropathy, pulmonary hypertension, and pulmonary fibrosis. Progressive pulmonary fibrosis may lead to respiratory failure, and abnormal GI motility may make nutrition difficult.

Cardiopulmonary complications are the most common cause of death in children with systemic sclerosis, typically heart failure secondary to lung disease.[22,23] Renal crisis is another serious complication (not commonly seen in children), and early initiation of antihypertensive therapy with angiotensin-converting enzyme inhibitors is essential.

Imaging

Significant pulmonary disease often occurs with little to no symptoms and an unremarkable chest radiograph. Thus pulmonary function tests (PFTs) and high-resolution chest CT (HRCT) are essential for early identification of lung disease when it is still treatable. Cardiac catheterization is often necessary to diagnose and assess the severity of pulmonary hypertension. Barium swallow and an upper GI series with small bowel follow-through are important to assess the extent of esophageal and small bowel dysmotility and dysfunction.

Management

Systemic sclerosis is challenging to treat as the disease is often far advanced before patients come to medical attention. Thus a thorough evaluation of all organ systems (even when there appears to be no symptoms) is necessary. Therapy is directed at both halting or reversing the underlying disease process, as well as reducing morbidity from disease complications. Acid blockade to control gastroesophageal reflux and prevention of microaspiration are important in patients with GI tract

involvement. Patients with severe Raynaud phenomenon may require vasodilation with calcium channel blockers, sildenafil, or iloprost. In patients with pulmonary hypertension, prostanoids and bosentan (a dual endothelin receptor antagonist) may reduce right ventricular and pulmonary artery pressures. Rapid initiation of angiotensin-converting enzyme inhibitors significantly improves the prognosis for patients in renal crisis.

For treating the underlying disease, the approach is similar to the treatment of other pediatric rheumatic diseases, but the response may be variable. High-dose corticosteroid therapy, methotrexate, mycophenolate mofetil, cyclophosphamide, and rituximab have been used. Corticosteroid therapy must be used with caution in patients with renal involvement, as it has been associated with renal crisis in adults. In severe refractory cases, hematopoietic stem cell transplantation (HSCT) has been successful for treatment of the skin disease.[24]

Unfortunately, gastrointestinal and pulmonary damage are rarely reversible and may be the cause of significant morbidity and mortality.

Mixed Connective Tissue Disease

Children may have overlapping features of different rheumatic diseases. The most well-characterized “overlap syndrome” is termed *mixed connective tissue disease* (MCTD), which can have features of JIA, SLE, JDM, and systemic sclerosis. Characteristic laboratory findings are a high-titer ANA (>1 : 320) and anti-RNP antibodies. Management is governed by which organs are affected and the severity of involvement.

Raynaud Phenomenon

Raynaud phenomenon is a triphasic color change (white, blue, red) typically in the fingers and toes due to transient vasoconstriction. It can occur as a primary process or secondary to an underlying rheumatic disease, most commonly lupus, scleroderma, or vasculitis. If the vasospasm persists, it may compromise the digits and require ICU intervention, including vasodilating agents such as iloprost, to prevent digit loss.

Antiphospholipid Syndrome

Clinical Presentation

Antiphospholipid syndrome (APS) is an autoimmune, prothrombotic state characterized by arterial or venous thrombosis, pregnancy morbidity, and specific laboratory features.[25] It may occur as a primary disorder, secondary to other autoimmune diseases (typically SLE), or in the setting of infection or malignancy. The clinical presentation depends on the site and type of vascular involvement and accompanying nonthrombotic manifestations. Venous thrombosis occurs most commonly in pediatric patients and can present in various ways including superficial thrombophlebitis, deep vein thrombosis, pulmonary thromboembolism, and cerebral venous sinus thrombosis. Arterial occlusion occurs less commonly and may also present in a variety of ways, including stroke, renal thrombotic microangiopathy, myocardial infarction, bone infarction, or mesenteric artery

thrombosis. Nonthrombotic clinical features are extremely variable but include cytopenias; neurologic abnormalities (movement disorders, migraine, transverse myelitis); skin findings (livedo reticularis, cutaneous necrosis, skin ulcerations); valvular heart disease; and renal involvement (hypertension, hematuria). Catastrophic antiphospholipid syndrome (CAPS) refers to the acute onset (<1 week) of small vessel occlusion affecting three or more organ systems leading to multiorgan failure.

Laboratory Studies

For any child presenting with a vascular thrombosis, a full hypercoagulability workup should be undertaken (see also Chapter 92). To diagnose APS, children must have one or more of the characteristic laboratory features: positive anti-cardiolipin antibodies, anti-β_2 glycoprotein antibodies, or lupus anticoagulant. As these APL antibodies can be transiently elevated in the setting of infection, a definite diagnosis of APS requires these be persistently elevated on two or more occasions 12 weeks apart.

Management

For children with vascular thrombosis due to APS, anticoagulation is typically initiated with unfractionated heparin. Lupus anticoagulant can prolong the activated partial thromboplastin time (aPPT); therefore monitoring antifactor Xa levels may be a more reliable measure of therapeutic anticoagulation. For acute, severe thrombotic events, thrombolytic therapy, such as tissue plasminogen activator, has been used successfully in children.[26]

Given the high mortality rate in CAPS, aggressive therapy is essential and should include anticoagulation, high-dose corticosteroids, and plasma exchange; IVIG, cyclosphosphamide, and rituximab may be of additional benefit.[27,28]

Systemic Vasculitis

The vasculitides are a heterogenous group of disorders that can be classified in various ways, including by size of the affected vessels and by characteristic laboratory features (Table 106.1). These disorders previously had high morbidity and mortality rates, but advances in treatment have led to markedly improved prognosis in pediatric patients.[29] The most common forms of primary vasculitis in children are Henoch-Schönlein purpura (HSP) and Kawasaki disease (KD), but children can develop granulomatosis with polyangiitis (GPA), microscopic polyangiitis (MPA), polyarteritis nodosa (PAN), and Takayasu arteritis (TA).

TABLE 106.1

Autoantibody Profiles for Vasculitis Associated With Various Autoimmune Diseases

	ANA	Ds-DNA	Smith	ANCA	Complement
SLE	+++	+ in 40%-80%	+ 50%-60%	Usually −	Low
GPA	− or weakly +	−	−	80% + (PR3)	Normal
MPA	− or weakly +	−	−	65% + (MPO)	Normal
Polyarteritis	−	−	−	Usually −	Normal
Takayasu arteritis	−	−	−	−	Normal

S-JIA	–	–	–	–	Normal–high

ANA, antinuclear antibody; *ANCA*, antineutrophil cytoplasmic antibody; *Ds-DNA*, double-stranded DNA; *GPA*, granulomatosis with polyangiitis; +, positive; −, negative; *MPA*, microscopic polyangiitis; *MPO*, myeloperoxidase; *PR3*, proteinase-3; *S-JIA*, systemic juvenile idiopathic arthritis; *SLE*, systemic lupus erythematosus.

Henoch-Schönlein Purpura

HSP is an immunoglobulin A–mediated small vessel vasculitis, often triggered by a preceding infection. The classic clinical features include palpable purpura predominantly on the lower extremities, arthritis or arthralgias, abdominal pain, and hematuria. Most cases are mild and resolve spontaneously. However, rapidly progressive glomerulonephritis and GI complications, including intussusception, necrosis, and perforation, may occur. Rarely, pulmonary hemorrhage and CNS involvement have been reported.[30,31]

Laboratory tests are nonspecific, usually showing only mildly elevated white blood cell counts and inflammatory markers. Coagulation studies and platelet counts are normal. The serum immunoglobulin A (IgA) level may be elevated, and in unclear or severe cases, a skin or renal biopsy can be performed and should demonstrate IgA deposition.

Treatment is primarily supportive, but IV high-dose corticosteroids are used for abdominal pain with vomiting or concern for suspected intussusception. In severe, or refractory cases, additional therapy may include cyclophosphamide, azathioprine, cyclosporine, IVIG, and plasmapheresis.

Kawasaki Disease

KD is a childhood vasculitis characterized by acute onset of fever for at least 5 days, conjunctival injection, cervical lymphadenopathy, rash, and extremity changes (erythema, edema, or desquamation). The disease has three phases: the acute febrile phase (10–14 days), the subacute phase (2–4 weeks), and the convalescent phase (months to years). The most serious complication of KD is coronary artery aneurysms, which occur most commonly in the subacute phase. Patients younger than 12 months old are at the highest risk for developing aneurysms but may not meet the full criteria for KD.[32] Some children present with pericarditis or myocarditis; in severe cases this may progress to congestive heart failure.[33] Patients can also present with KD shock syndrome (KDSS), which can be difficult to distinguish from septic shock or toxic shock syndrome. KDSS may be refractory to IVIG, and patients may then require additional therapy, such as infliximab.[34] KD can also be complicated by MAS (discussed later).

ESR and CRP are usually markedly elevated in KD. Once IVIG has been administered, ESR is no longer a reliable marker of inflammation and CRP is the best marker of disease activity. Platelet counts may initially be low but can rise to more than 1,000,000/uL. Anemia and elevated transaminases are also common. Serial echocardiography is the best way to monitor the coronary vessels for signs of inflammation, dilation, or aneurysms.

Prompt identification and treatment of KD with IVIG (2 g/kg, maximum dose 70 g) and high-dose aspirin (80–100 mg/kg/day divided 4 times daily) usually helps prevent aneurysm formation. Long-term use of low-dose aspirin (3–5 mg/kg/day) is

recommended once the acute illness is resolved.[35] For cases refractory to IVIG (up to 10% of cases), the addition of high-dose corticosteroids and antitumor necrosis factor alpha (anti-TNFα) agents, such as infliximab, are effective. Predictors of poor response to IVIG include young age at diagnosis, hyponatremia, thrombocytopenia, elevated neutrophil count, high AST, and high CRP.[36]

In cases complicated by myocarditis, supportive care including inotropes and diuretic therapy may be necessary. Anticoagulation should be considered in the setting of large aneurysms to prevent further cardiovascular sequelae.[37]

Granulomatosis With Polyangiitis

GPA (formerly known as Wegener granulomatosis) is a granulomatous vasculitis that targets the sinuses and middle ear, lungs, and kidneys. Severe manifestations include subglottic stenosis with dyspnea and stridor, pulmonary hemorrhage, necrotizing cavitary lung lesions, and rapidly progressive necrotizing glomerulonephritis. Additional symptoms can include fever, weight loss, hearing loss, conjunctivitis, purpura or petechiae, arthritis, headache, and dizziness. For a patient presenting with pulmonary-renal syndrome, other diagnoses should be considered in addition to GPA including MPA, Goodpasture syndrome, and SLE (Table 106.2).

TABLE 106.2

Pulmonary-Renal Syndromes

Diagnosis	Pulmonary Findings	Renal Findings	Other Organ System Involvement	Laboratory Findings
GPA	Cavitating lung lesions, pulmonary hemorrhage	Pauci-immune necrotizing glomerulonephritis	Sinus, airways	Usually cANCA positive (PR3)
MPA	Pulmonary hemorrhage	Pauci-immune necrotizing glomerulonephritis	Skin, CNS	Usually pANCA positive (MPO)
Goodpasture syndrome	Pulmonary hemorrhage	Anti-GBM positive glomerulonephritis	None	Anti-GBM positive
SLE	Pulmonary hemorrhage	Proliferative or membranous changes; marked immune complex deposition	Multisystem disease	ANA positive, anti-dsDNA positive, anti-Sm positive, low complements

ANA, antinuclear antibody; *GBM*, glomerular basement membrane; *GPA*, granulomatosis with polyangiitis; *MPA*, microscopic polyangiitis; *MPO*, myeloperoxidase; *PR3*, proteinase-3; *SLE*, systemic lupus erythematosus.

Antineutrophil cytoplasmic antibodies (ANCAs) target antigens within the cytoplasm of granulocytes. Cytoplasmic ANCAs (cANCAs) are seen in about 80% of pediatric patients with GPA. Antiproteinase-3 (PR3) antibodies are more specific and are seen in 60% of children with GPA.[38] These antibodies often correlate with disease activity. WBC and inflammatory markers are typically elevated. Urinalysis may show evidence of glomerulonephritis, including proteinuria, hematuria, and red blood cell casts. Renal biopsy can demonstrate necrotizing glomerulonephritis, with minimal immune deposits (“pauci-immune”) on immunofluorescence staining.

Imaging is necessary to establish the extent of upper and lower airway involvement. Sinus involvement may not be clinically apparent, and CT or MRI can be helpful to identify sinus disease. To assess the extent of lung involvement, HRCT can identify cavitary lung lesions and pulmonary hemorrhage, as well narrowing of

the trachea, bronchi, and bronchioles.

Immunosuppressive therapy, including cyclophosphamide and high-dose IV corticosteroids, reduces mortality and induces remission in the majority of patients. Recently, there has been increasing use of rituximab (375 mg/m^2 weekly for 4 doses or 750 mg/m^2 2 doses given 2 weeks apart) as induction therapy for GPA as it targets the B lymphocytes thought to be pathogenic in this disease. Early use of rituximab may obviate or lessen the need for cyclophosphamide. Traditionally, cyclophosphamide has been given as induction therapy, either enterally (2 mg/kg/day) in severe, life-threatening cases, or intravenously (various dosing protocols, typically 750 mg/m^2 monthly for 6 months). In severe cases, plasmapheresis may also be indicated. Azathioprine or MMF is used for milder cases and for long-term maintenance therapy.

Microscopic Polyangiitis

This small-vessel vasculitis typically affects the lungs, kidneys, GI tract, central and peripheral nervous systems, skin, and muscles. Patients often present with constitutional symptoms such as fever, fatigue, and weight loss. Severe manifestations include pulmonary hemorrhage, GI bleeding or infarction, stroke, necrotizing glomerulonephritis, and renal failure.

The diagnosis is based primarily on clinical features, but laboratory tests may also be helpful. Perinuclear ANCAs (pANCAs) are present in approximately 65% of patients with MPA, particularly for the neutrophil component myeloperoxidase (MPO). However, these antibodies can be present in other rheumatic diseases, such as SLE or GPA, and in conditions such as inflammatory bowel disease.[39] A biopsy of affected tissue (including lung, kidney, muscle, nerve, or skin) demonstrating pauci-immune, small-vessel vasculitis confirms the diagnosis.

The treatment approach to MPA is the same as for GPA: High-dose corticosteroids plus a corticosteroid-sparing agent are typically used to induce remission. Cyclophosphamide and rituximab are used in severe cases, while azathioprine or MMF is used for milder cases and for long-term maintenance therapy.

Polyarteritis Nodosa

PAN is a vasculitis affecting medium-sized vessels. It is rare in childhood but should be considered in any child presenting with unexplained fever, rash, hypertension, and abdominal pain. Skin manifestations vary, including painful nodules, purpura, petechiae, or patchy edema. Muscle tenderness, arthritis, and arthralgia may also occur. GI vasculitis usually presents with abdominal pain, hemorrhage, necrosis, or perforation. CNS features can be severe and include psychosis, seizures, strokes, or neuropathy. Cardiac involvement, including coronary arteritis, is more common in children.

There are no associated antibody tests in PAN. A biopsy of affected tissue (typically muscle, nerve, skin, kidney, or GI tract) can be diagnostic, demonstrating necrotizing arteritis of small- or medium-sized muscular arteries.

Angiography is important for diagnosing and assessing the extent of vessel involvement. Conventional angiography is the gold standard, but there is an increasing role for less invasive imaging, such as CT or magnetic resonance angiography. Characteristic pathologic findings include vessel stenosis, occlusion,

and aneurysms.

The treatment approach is the same as that used in GPA or MPA.

Takayasu Arteritis

TA causes granulomatous inflammation of the aorta and its major branches. In the early, inflammatory phase, patients present with fever, fatigue, weight loss, headaches, abdominal pain, and hypertension. Subsequent vascular changes, such as mural thickening, aneurysm formation, and stenosis, lead to end-organ ischemia. Symptoms and signs can include absent pulses, angina, abdominal pain and bloody diarrhea (due to mesenteric artery involvement), visual changes, claudication, myocardial infarction, encephalopathy, and stroke.

Ultrasonography, magnetic resonance angiography, and CT are all helpful for diagnosing or managing TA, establishing the severity and extent of disease, and monitoring response to therapy. In some cases, conventional angiogram may be necessary.

The treatment approach is the same as for GPA, but there is an increasing role for anti-TNFα therapy, particularly infliximab. Angioplasty and stent placement have been successful and improve survival rates in pediatric TA.[40] In severe cases, aortic reconstruction is necessary.

Primary Vasculitis of the Central Nervous System

Primary vasculitis or angiitis of the CNS is characterized by isolated inflammation of vessels in the CNS with no other organ involvement. In pediatric patients with small vessel disease, the most common presenting feature is seizure. In medium-large vessel disease, patients may present with stroke, headache, cranial neuropathy, or movement disorders. The diagnosis should be considered in a child with unexplained CNS deterioration, especially if other diagnoses such as infection or metabolic conditions have been excluded.[41]

Angiography can be helpful for diagnosis but may not detect small vessel disease, in which case a brain biopsy may be required.

Aggressive treatment with high-dose corticosteroids and cyclophosphamide has been shown to improve survival. MMF is typically used for long-term maintenance therapy.

Rheumatic Diseases: Conditions and Complications in the ICU

There are many serious complications of pediatric rheumatic diseases and complications associated with the treatment of these conditions. Many of these were introduced earlier. The following section provides a more thorough discussion of the conditions and complications that are most relevant in the intensive care setting.

Infections

Children with rheumatic diseases are at high risk for infection due to immune dysfunction from their underlying disease process and chronic immunosuppressive therapy. Infection is a common reason for ICU admission and a leading cause of

death in patients with active rheumatic disease, particularly SLE.[42,43] Children being treated for rheumatic diseases may not manifest typical signs of infection, such as fever. As many rheumatic diseases cause hypertension, a relative decline in blood pressure is concerning for sepsis, even if the child remains normotensive. Similarly, diseases such as SLE cause a low WBC count, so a relative rise may indicate infection even without a true leukocytosis. Given the underlying inflammatory disease, inflammatory markers may also be difficult to interpret. Therefore a high index of suspicion for infection and early initiation of broad-spectrum antimicrobial therapy are warranted.

Patients with rheumatic diseases are susceptible to typical, community-acquired bacteria such as *Staphylococcus aureus, Streptococcus pneumoniae,* and *Haemophilus influenzae,* as well as gram-negative enteric bacteria. However, due to chronic immunosuppression, they are also at high risk for opportunistic infections, with *Pneumocystis jiroveci, Mycobacterium tuberculosis, Aspergillus* or *Mucor* species, and cytomegalovirus. Common organisms can be found in unusual sites, such as staphylococcal endocarditis, or unusual organisms can be identified in typical sites of infection, such as mucormycosis of the sinuses. Before starting antimicrobial therapy, body fluids and specimens should be obtained for culture. With suspected pulmonary infection, HRCT and bronchoscopy with bronchoalveolar lavage should be considered early as lung lesions can progress quickly into severe, acute lung injury and patients can rapidly decompensate. For patients receiving immunosuppressive therapy, *P. jiroveci* pneumonia prophylaxis is typically recommended. In patients with a history of *Herpes zoster* or fungal infection, antiviral and antifungal prophylaxis should also be considered.

Macrophage Activation Syndrome

MAS is a severe, life-threatening complication of childhood rheumatic disease, primarily soJIA. It may also occur in the setting of infection and malignancy. In rheumatic disease, MAS may be present at the time of diagnosis, disease flare, or change in medical therapy or with intercurrent infection. Diagnosis can be difficult, as findings can be confused with infection and sepsis or acute exacerbations of the underlying disease process.[44] Therefore a high index of suspicion is necessary. MAS can start with no symptoms, but rather a mild trend of abnormal changes in the laboratory tests, and then rapidly progress to full-blown, severe disease.

Patients typically become ill and then become more acutely ill with unremitting high fever (different from the quotidian pattern of soJIA), lymphadenopathy, hepatosplenomegaly, cytopenias, and coagulopathy, and they may even have altered mental status. Severe manifestations include seizures, coma, and gastrointestinal bleeding, as well as heart, lung, or kidney failure. The mortality rate ranges from 4% to 15%.[44]

Laboratory evaluation typically reveals cytopenias (at least two of three cell lines), elevated transaminases, coagulopathy, elevated triglycerides, elevated lactate dehydrogenase, and most significantly, a elevated ferritin level (often >10,000 ng/mL). A falling ESR, especially with a high CRP, is concerning for MAS and is secondary to low fibrinogen in the setting of consumptive coagulopathy. Natural killer (NK) cell activity is low or absent. Soluble IL-2 receptor levels are typically elevated. The pathognomic feature of MAS is hemophagocytosis on bone marrow

aspirate or biopsy, although this may not be present early in the disease course.

MAS is a form of secondary hemophagocytic lymphohistiocytosis (HLH)—a systemic inflammatory storm characterized by overwhelming expansion and activation of T lymphocytes and macrophages, with decreased NK and cytotoxic T-cell function. Familial HLH is an autosomal recessive disorder associated with mutations of the perforin or MUNC 13-4 genes. Genetic testing can differentiate the two disorders but often takes weeks to perform. Risk factors for familial HLH include young age (younger than 2 years), significant CNS disease, consanguinity, or family history of death due to unidentified febrile illness.[45]

Aggressive treatment of MAS is essential. Until recently the standard therapy consisted of rapid initiation of high-dose pulse IV methylprednisolone therapy (30 mg/kg/day for 3 days, maximum dose 1000 mg, then 1 to 2 mg/kg/day divided twice daily) with a slow corticosteroid taper plus IV cyclosporine 3 to 5 mg/kg/day. More recently, anakinra (2 to 4 mg/kg IV every 6 to 24 hours) is being used in place of cyclosporine and is rapidly effective.[45]

Airway Compromise

Rheumatic conditions can cause airway compromise due to obstruction from inflammation or inability to protect the airway because of muscle weakness. This may be indolent or rapid in onset. Intubation can be challenging, and tracheostomy may be necessary.

Disease such as JIA, SLE, and GPA and rare diseases such as relapsing polychondritis can be complicated by airway involvement leading to obstruction in severe cases.[46] Although rare, oropharyngeal obstruction can occur in SLE due to angioedema with acute mucosal swelling of the pharyngeal and laryngeal tissues.[47] Cricoarytenoid arthritis is a rare complication in JIA that can cause airway obstruction manifested by hoarse voice, stridor, and dyspnea.[48] Subglottic stenosis affects 10% to 20% of patients with GPA and is five times more common in pediatric than adult-onset disease. A conservative approach with medical therapy and local interventions such as intralesional steroid injections and dilation have been used successfully and may obviate the need for surgical reconstruction.[49] Relapsing polychondritis, a disorder of recurrent cartilaginous inflammation, affects both the small and large airways and can cause upper or lower airway obstruction.[46]

Muscle weakness can also lead to airway compromise. In JDM, muscle weakness of the palate, pharynx, larynx, and upper third of the esophagus can lead to dysphagia, dysphonia, inability to manage secretions, and airway compromise severe enough to warrant intubation. Muscle weakness can also mask signs of respiratory distress.

Pulmonary Involvement

Infection is the most common lung-related complication in pediatric rheumatic disease, but there are many other associated pulmonary complications including interstitial lung disease, pulmonary fibrosis, pleuritis and pleural effusion, alveolar hemorrhage, and pulmonary embolism.

Interstitial Lung Disease

Children with rheumatic diseases, including SLE, soJIA, JDM, and systemic sclerosis, may rarely develop interstitial lung disease (ILD), which in severe cases can progress to pulmonary fibrosis. Patients may be asymptomatic or present with fever, cough, respiratory distress, or pleuritic chest pain. Chest radiographs may show interstitial changes but are not always sensitive enough to detect ILD (Fig. 106.1). HRCT is a more sensitive study and may reveal characteristic findings, such as basilar ground-glass opacities, honeycombing, subpleural nodules, and bronchiectasis.[50] Pulmonary function testing is also helpful in diagnosing and monitoring ILD. Children with rheumatic disease-related ILD may develop pulmonary hypertension and require vasodilator therapy (Fig. 106.2).[23] Patients with severe ILD are treated with aggressive immunosuppression and supportive therapy, and in some cases they may require extracorporeal membrane oxygenation (ECMO).

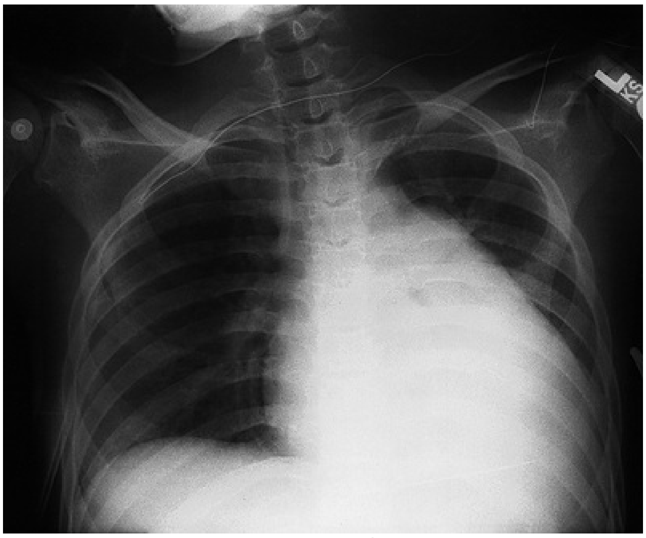

FIG. 106.1 Portable chest radiograph of a 16-year-old girl with systemic lupus erythematosus. Lupus pneumonitis is reflected by infiltrate in the right upper lobe and bilateral diffuse interstitial changes. Pleural fluid suggested by haziness over the left lower lobe, as well as blunted left costophrenic angle (not shown), was confirmed by bilateral decubitus films.

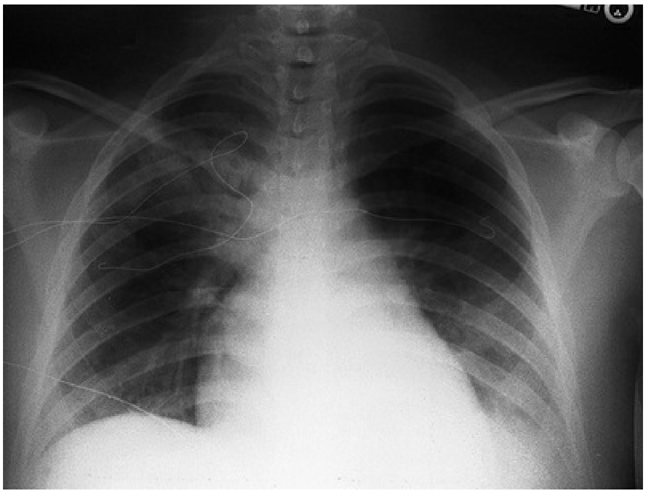

FIG. 106.2 Portable chest radiograph of a 12-year-old girl with scleroderma. The patient arrived at the ICU with sudden onset of orthopnea and thrombocytopenia. Cardiomegaly was observed. Echocardiography revealed pericardial effusion. However, pulmonary vascularity was normal in this patient. Physical examination revealed sclerodactyly. The patient eventually developed cor pulmonale as a result of pulmonary hypertension. Inflammatory changes suggestive of other collagen vascular diseases may be seen in the early course of scleroderma. Use of pulse IV methylprednisolone reduced these early inflammatory changes, although as an outpatient the patient maintained stable right-sided heart disease that was not responsive to immunosuppressive medication, consistent with scleroderma.

Pleuritis and Pleural Effusions

Pleuritis, with or without pleural effusion, is a common manifestation of rheumatic disorders in children. Patients typically have pleuritic chest pain, respiratory distress, and orthopnea. On examination, they may have distant heart sounds, friction rub, dullness with chest percussion, and reduced air entry. Pleural effusions can be sufficiently large to compromise lung function, requiring chest tube placement. Most respond to treatment of the underlying inflammatory disease, but occasionally aspiration and drainage of effusions are necessary.

Pulmonary Hemorrhage

Acute alveolar hemorrhage is a serious complication of systemic vasculitides, including GPA, MPA, and SLE, with a mortality rate around 70%.[51] Presenting symptoms typically include dyspnea and hemoptysis but are not always present. Acute pulmonary hemorrhage can be rapidly progressive and catastrophic, leading to acute hypoxemic respiratory failure and hemorrhagic shock. A sudden decline in hemoglobin suggests the diagnosis. Evaluation for bacterial, viral, and fungal infection should be undertaken as pulmonary infections may trigger hemorrhage. Chest radiography typically reveals diffuse alveolar airspace filling defects, although in milder cases there may only be focal abnormalities. HRCT is more sensitive than chest radiography and typically reveals ground-glass opacities. Although not generally obtainable in critically ill patients, pulmonary function tests should reveal an elevated diffusion capacity. Supportive care includes positive pressure ventilation

with high positive end-expiratory pressure, blood transfusions to maintain hemodynamic stability, and close monitoring. Despite the need for systemic heparinization, ECMO has been found to be safe and life saving in children with pulmonary hemorrhage who fail conventional therapy.[52,53] Treatment of the underlying rheumatic disease is critical and typically involves a combination of high-dose IV corticosteroid therapy, cyclophosphamide, and rituximab. In antibody-mediated vasculitides, plasmapheresis acts by removing pathogenic antibodies from the circulation and is an effective therapeutic intervention.[53,54]

Pulmonary Embolism

Patients with APLs, either primary or secondary to conditions such as SLE, are at increased risk for pulmonary embolism and other thrombotic events.[55] Nephrotic syndrome, associated with SLE, also increases risk of pulmonary embolism due to renal loss of anticoagulant factors. Patients typically present with pleuritic chest pain, tachypnea, tachycardia, and hypoxia but can sometimes be asymptomatic. Chest CT with angiography is the most helpful diagnostic test. Early intervention with systemic thrombolytics, including unfractionated heparin and tissue plasminogen activator, improves survival in pediatric patients.[56]

Cardiovascular Events

Pericarditis and Pericardial Tamponade

Pericarditis can occur in the setting of various rheumatic diseases, including soJIA, SLE, and KD. Patients present with precordial chest pain, fever, and tachycardia, and on examination they may have distant heart sounds and a friction rub. Acute pericarditis with effusion may lead to cardiac tamponade, with tachycardia, narrow pulse pressure, and clinical signs of poor cardiac output. In severe cases or if there is concern for an underlying infection, pericardiocentesis may be necessary.[57] Chronic pericarditis may cause restrictive cardiac disease. Evaluation for pericarditis includes ECG and ECHO. Symptoms should improve with medical management of the underlying systemic inflammatory disease, including nonsteroidal antiinflammatory drugs (NSAIDs), corticosteroids, and immunosuppression.

Myocarditis

Although rare, patients with rheumatic disease including SLE, JIA, JDM, and vasculitis may present with myocarditis, manifested by poor cardiac output and congestive heart failure.[57,58] Symptoms include fatigue, exercise intolerance, tachycardia, and respiratory distress, with rales and hepatomegaly on examination. Chest radiography may demonstrate cardiomegaly with pulmonary edema and ECHO can show diminished ventricular systolic function. Management involves diuresis, inotropic support, and aggressive immunosuppressive therapy.[58]

Valvular Disease

Libman-Sacks endocarditis is a valvular abnormality that can occur in SLE, usually associated with the presence of APLs. It is a verrucous endocarditis, in which fibrinoid nodules form on the cardiac valves, most frequently on the mitral valve.[57] Vegetations and valvular thickening can lead to severe regurgitation and stenosis.

Echocardiography is the best diagnostic study; in some cases, a transthoracic study may not be sensitive enough to detect valvular disease and a transesophageal study is necessary.[59,60] Many patients respond to medical treatment of the underlying SLE, but in severe cases valve replacement surgery may be indicated.

Arrhythmias

SLE is associated with an increased risk for conduction abnormalities, including premature atrial beats, supraventricular tachycardia, atrioventricular block, and right bundle branch block. This is best diagnosed by ECG and ECHO. Patients usually respond to pharmacologic antiarrhythmics. Pacemakers are indicated for complete atrioventricular block, particularly in neonatal lupus.[19]

Acute Coronary Syndrome

There is a well-recognized, increased risk for acute myocardial infarction in SLE secondary to premature atherosclerosis, probably related to the combined effect of disease-related dyslipidemia, coronary artery inflammation, and long-term corticosteroid therapy.[61] In any child with SLE presenting with chest pain or dyspnea, myocardial infarction should be considered. ECG may demonstrate ST segment elevation and laboratory testing, including serum troponin, may be helpful. The underlying SLE should be treated; cardiology consultation is beneficial for management and long-term cardiac monitoring.

In KD, there is also an increased risk for acute myocardial infarction secondary to coronary artery aneurysms. Thrombosis or rupture of coronary aneurysms leads to myocardial ischemia and can occur many years after the KD diagnosis, even in adulthood.[62] Giant aneurysms (>8 mm in diameter) have the poorest prognosis. In severe cases, surgical intervention for bypass grafting has been successfully performed in children.[63]

Endocrine Dysfunction

Endocrine issues can complicate many of the rheumatic diseases. One of the most serious complications is adrenal insufficiency due to abrupt discontinuation of chronic steroid therapy.[64,65] Rapid initiation of stress dose corticosteroids in the setting of acute illness or surgery is essential. Diabetes may also occur in the setting of steroid treatment, requiring insulin therapy. Thyroid disease can present as either hypothyroidism or hyperthyroidism and is a common complication of JIA and SLE.

Gastrointestinal Involvement

Gastrointestinal Hemorrhage

The vasculitides and other systemic inflammatory diseases increase the risk for acute and subclinical GI hemorrhage. Medications, such as high-dose corticosteroids and NSAIDs, also increase the risk of GI bleeding. In the setting of suspected acute hemorrhage, large-bore IV access should be obtained and transfusion of blood products may be necessary to maintain hemodynamic stability. Early GI and surgical consultation are advised. Imaging-guided embolization of bleeding vessels may be necessary in severe cases. Up to 30% of patients with HSP develop GI hemorrhage,

although severe hemorrhage, irreducible intussusception, and perforation are rare.[66]

Acute Abdominal Pathology: Peritonitis, Serositis, and Intestinal Perforation

Children with rheumatic disease are at increased risk of morbidity and mortality from acute abdominal pathology.[67] Nonbacterial peritonitis and serositis of the abdominal organs are common manifestations of SLE (≈20% of pediatric patients) and JIA, particularly soJIA. Patients may present with severe symptoms, including a surgical abdomen. However, immunosuppressive therapy can mask clinical signs and symptoms, leading to delayed diagnosis; therefore a high index of suspicion for severe pathology is necessary.[68] Patients are also at risk for infectious pathology, such as bacterial peritonitis with abscess formation, and for intestinal perforation. In cases in which infection and perforation have been excluded and symptoms are thought to relate to noninfectious serositis, the underlying disease should be treated aggressively to bring symptoms under control.

Severe acute pancreatitis may complicate pediatric rheumatic diseases, particularly SLE.[69] It may be disease related or secondary to medications, such as high-dose corticosteroids and azathioprine.

In patients with nonlocalizing abdominal pain, pancreatitis should be considered and appropriate laboratory screening and imaging performed to look for inflammation, stones, and pseudocysts. Inciting drugs should be avoided if possible.

Renal Involvement

Most vasculitic disorders, including SLE, GPA, MPA, and HSP, can affect the kidneys. Renal disease may be present at the time of initial diagnosis or may evolve later. It can manifest in various ways, with oliguria or anuria, hematuria, hypertension, nephrotic syndrome, and renal failure. Laboratory evaluation includes determination of serum electrolytes, blood urea nitrogen, creatinine, and albumin; urinalysis; spot urine protein/creatinine ratio (ideally first morning void); and 24-hour urine protein and creatinine collection. Depending on the clinical presentation, complete blood cell count, ANA, complement levels (C3 and C4), ANCAs, MPO, PR3, and antiglomerular basement membrane antibodies may also be important. Renal biopsy is extremely helpful in diagnosing pediatric rheumatic diseases and has important implications for treatment. The extent and type of renal involvement, especially in diseases such as SLE, GPA, and MPA, help determine the treatment course and intensity of immunosuppression. In cases complicated by bleeding diathesis or severe hypertension, however, a renal biopsy may be contraindicated.

Aggressive treatment of the underlying rheumatic disease should bring renal manifestations under control. Severe renal involvement in SLE, GPA, and MPA typically warrants treatment with high-dose IV steroid therapy, cyclophosphamide, and often rituximab. For ANCA-associated vasculitides with severe renal involvement, plasmapheresis is an effective intervention that improves rates of survival.[70] Hypertension can be severe, leading to neurologic and other end-organ complications, and must be managed aggressively with antihypertensive therapy, in severe cases by continuous drip. Patients with rheumatic disease may rarely present with end-stage renal disease at diagnosis or progress to end-stage renal disease, requiring dialysis. Renal transplantation has been successfully performed in

pediatric patients, but there is a risk of disease recurrence.[71,72]

Central Nervous System Involvement

The CNS can be affected in many pediatric rheumatic diseases and can manifest in various ways including seizure, headache, stroke, psychosis, encephalopathy, and movement disorders.[73,74] When neurologic symptoms present, especially in immunosuppressed patients, CNS infection (viral, bacterial, and fungal) must be considered. In addition, the presence of APLs is highly associated with neurologic symptoms, especially stroke, seizure, headache, and movement disorders. APLs can be present in the setting of primary APS or secondary to another rheumatic disease; APLs should be rescreened whenever new neurologic symptoms present. Imaging may be helpful in identifying stroke but not sensitive enough to detect small vessel vasculitic changes; a brain or meningeal biopsy is sometimes necessary (Fig. 106.3). For neurologic manifestations of rheumatic disease, treatment of the underlying disease should typically bring symptoms under control. Aggressive immunosuppression is generally indicated for CNS involvement, such as lupus cerebritis, including high-dose IV steroid therapy and cyclophosphamide. Plasmapheresis may be necessary in severe cases. Concurrent use of anticonvulsant and/or antipsychotic medications may be necessary. In the setting of thrombotic stroke, anticoagulation is generally indicated.

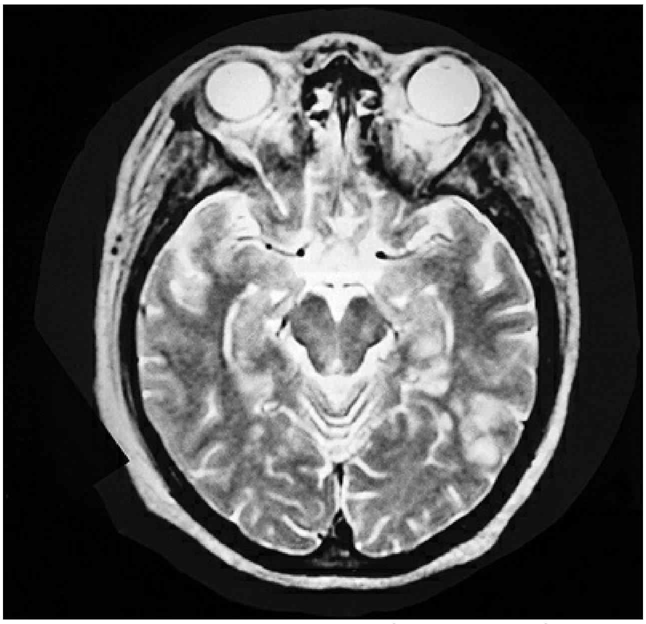

FIG. 106.3 Magnetic resonance image of the brain of a 16-year-old girl with systemic lupus erythematosus. This image was obtained after the patient was stabilized. Multiple areas of increased signal are scattered throughout both cerebral hemispheres, consistent with ischemic infarctions resulting from lupus cerebritis. Other views demonstrated similar infarcts in the brain stem and cerebellar hemisphere. Magnetic resonance angiography obtained at the same time revealed normal vasculature, suggesting pathologic involvement of brain tissue but sparing of vessels. The patient responded well to pulse IV methylprednisolone and cyclophosphamide, with no residual neurologic deficit.

The eye can be involved in a number of ways, including conjunctivitis, scleritis, episcleritis, uveitis, and retinal vasculitis.[75] Ophthalmology consultation is often helpful.

Hematologic Involvement

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura (TTP) is a rare, life-threatening hematologic disorder that can be inherited or acquired. It is associated with SLE, especially in pediatric patients. Diagnosis is based on five clinical features: (1) thrombocytopenia and disseminated platelet aggregation, (2) microangiopathic hemolytic anemia, (3) neurologic abnormalities, (4) fever, and (5) renal disease.[76,77] The pathophysiology is based on dysfunction of the ADAMTS-13 enzyme, which normally cleaves von Willebrand factor (vWF) multimers. In TTP, there is a lack of vWF cleavage leading to an accumulation of vWF multimers, which bind to platelets leading to clot formation and end-organ damage. In congenital TTP, there is a deficiency of ADAMTS-13, while in acquired TTP an inhibitory autoantibody inactivates ADAMTS-13. In patients with clinical TTP, demonstrating reduced levels of ADAMTS-13 activity (<5%) is confirmatory. Treatment for TTP includes immunosuppression with corticosteroids and cyclophosphamide, as well as plasmapheresis, which significantly decreases the mortality rate.[76]

Complications of the Treatment of Rheumatic Diseases

Although the treatment of rheumatic disease is effective and often life saving, there are risks and complications related to treatment itself. High-dose steroid therapy may exacerbate hypertension and cause electrolyte imbalances (particularly sodium and fluid retention) and hyperglycemia. Corticosteroids can also impair neutrophil function, leading to increased susceptibility to infection. Long-term effects of corticosteroids include loss of bone density, with increased risk of compression fractures, and skin atrophy, with increased the risk of skin breakdown. As already discussed, a serious complication of chronic corticosteroid therapy, especially in the ICU setting, is adrenal insufficiency that may require stress-dose corticosteroid therapy.

Several medications cause gastric irritation and pancreatitis. GI prophylaxis with proton pump inhibitors and monitoring pancreatic and liver enzymes is recommended. Biologic therapies, such as infliximab or rituximab, may cause mild or severe hypersensitivity reactions, and patients must be monitored closely. In some cases, patients may need to be admitted to the ICU for medication desensitization protocols.[78]

Managing medications can be complex in critically ill patients with rheumatic disease. As many of the medications are cleared by the kidneys or affected by dialysis, this can have important implications for dosing. Balancing the complexities of the organ systems involved in rheumatic disease with the potential toxicities and interactions of therapy is best accomplished with a multidisciplinary approach.

Summary

In summary, rheumatic diseases manifest with a wide variety of presentations and can affect all organ systems. Pediatric intensivists therefore need a basic understanding of the most commonly seen conditions in pediatric rheumatology, including JIA, SLE, JDM, vasculitides, and scleroderma, as critically ill children may present to the ICU with new-onset rheumatic disease, disease flare, or complications. In addition, many of the therapies for rheumatic diseases have clinically significant side effects that may require close monitoring in the intensive care setting. The diagnosis of rheumatic disease is challenging and requires a thorough history and physical examination, as well as consideration of a broad differential diagnosis. Early identification and management can significantly reduce morbidity and mortality, and providers in the intensive care setting play a vital role in providing life saving interventions to children with rheumatic disease.

CHAPTER 107

Bacterial and Fungal Infections, Antimicrobials, and Antimicrobial Resistance

Deborah E. Franzon, Hayden T. Schwenk, Mihaela Damian

PEARLS

- In the pediatric ICU (PICU), appropriate dosing of antibiotics without delay decreases morbidity and mortality, the overall costs of treating the infection, and the emergence of resistance.
- Critically ill children exhibit altered pharmacokinetics with differences in volume of distribution and clearance that impact response to antimicrobial exposure.
- An important side effect of high-dose, long-term use of β-lactam agents in the PICU setting is neutropenia.
- Risk factors for *Candida* spp. bloodstream infections in the PICU, resulting in mortality rates as high as 44%, are presence of a central venous catheter, a diagnosis of malignancy, and receipt of either vancomycin or antimicrobials with activity against anaerobic organisms for more than 3 days. Guidelines suggest echinocandins as first-line therapy.
- Occult fungal infection should be considered in any patient with chemotherapy-neutropenia with fever persisting more than 96 hours despite empiric antibiotic therapy.
- Emergence of resistance organisms is increasing in critically ill patients, particularly vancomycin-resistant enterococcus, extended-spectrum β-lactamase producing enteric gram-negative bacteria, and multidrug-resistant pseudomonas, calling for the need to use alternative drug and dosing strategies.
- Antimicrobial stewardship programs that implement strategies to reduce unnecessary antimicrobial use can be cost-effective programs that address resistance in the ICU setting.

Because of the severity of illness of children in the pediatric ICU (PICU), there is little room for error in selecting the appropriate antimicrobial agent. It is important to treat infections aggressively to obtain the best clinical and microbiologic outcomes. Timing of antibiotic administration is important, and any delay in administration is associated with increased mortality and worse outcomes. The importance of timely administered, broad-spectrum empiric antimicrobials must be balanced with their potential to promote antimicrobial resistance. Because antibiotic resistance may lead to increased morbidity and mortality, as well as increased health care costs, de-escalation of antibiotics, based on microbiologic and susceptibility data, is imperative.[1] This chapter reviews the most clinically important classes of antibiotics and antifungals, including those currently under investigation and not approved by the US FDA for use in children. Mechanisms of resistance are reviewed, as are the strategies designed to meet the challenge of treating and preventive the development of resistant organisms. Many textbooks about infectious diseases have excellent in-depth reviews of antibiotic characteristics and are recommended for additional information.[2,3]

General Considerations for Antibiotic Therapy

Tissue penetration and dosing of antimicrobials are critical; pharmacokinetic (PK) and pharmacodynamic (PD) characteristics of different classes of antibiotics against different types of pathogens help determine the dosing regimen required for microbiologic and clinical cure.[4,5] Due to changes in both fluid dynamics and kidney perfusion, critically ill children exhibit altered pharmacokinetics with differences in volume of distribution and clearance that impact antimicrobial exposure. It is imperative to achieve appropriate concentrations of the antibiotic in relationship to the organism's minimum inhibitory concentration (MIC). Based on PK/PD characteristics, antibiotics can be classified as (1) concentration-dependent (fluoroquinolones, aminoglycosides); (2) time-dependent (β-lactams); and (3) both concentration- and time-dependent antibiotics (glycopeptides). These parameters are important to consider because the inappropriate dosing of antibiotics may facilitate the development of antibiotic resistance and increase the odds of morbidity and mortality.[6-9]

After an infection is suspected on the basis of the clinical, laboratory, and imaging characteristics of the child, appropriate cultures should be obtained. Broad-spectrum antibiotics should be administered empirically, according to the local susceptibility patterns. Data suggest that using active antibiotics in the appropriate dose without delay decreases morbidity and mortality, the overall costs of treating the infection, and the emergence of resistance. The relative activity of antimicrobial agents against gram-negative (Table 107.1) and gram-positive pathogens (Table 107.2) is provided, although clinicians should consult their local antibiogram.

TABLE 107.1

Antibiotic Activity for Gram-Negative Pathogens (0 to +++++)

Organism	Ticarcillin-Clavulanate	Piperacillin-Tazobactam	Ceftazidime	Ceftriaxone	Cefepime	Tobramycin	Ciprofloxacin	Merc
Escherichia coli	++++	++++	++++	++++	++++	++++	++++	++++
Klebsiella spp.	++++	++++	++++	++++	++++	++++	++++	++++

Enterobacter spp.	+++	+++	++++	++++	++	+++	++++	++++-
Pseudomonas aeruginosa[a]	+++	+	++++	++++	+++	++++	+++	++++
Acinetobacter spp.[b]	++	++	+++	+++	+++	++	++	++++
Stenotrophomonas[a]	+++	+	++	+	+++	++	++	+

[a]Trimethoprim-sulfamethoxazole is the most active antibiotic against *Stenotrophomonas* in vitro.

[b]Colistin may be effective in vitro against organisms resistant to all available agents, with limited data on efficacy and significant toxicities.[21]

Susceptibility data are averaged,[44-46,48,49] with local hospital data potentially much different from these values.

TABLE 107.2

Antibiotic Activity for Gram-Positive Pathogens (0 to +++++)

Organism	Ampicillin	Oxacillin	Cefazolin	Vancomycin	Linezolid
Methicillin-susceptible *Staphylococcus* spp. (*Staphylococcus aureus* or coagulase-negative staphylococci)	0	+++++	+++++	+++++	++++
Methicillin-resistant *Staphylococcus* spp.	0	0	0	+++++	++++
Enterococcus faecalis[a]	++++	0	0	++++	++++
Enterococcus faecium[a]	++	0	0	++++	++++

[a]For vancomycin-susceptible strains.

Susceptibility data are averaged,[40,44,50] with local hospital data potentially much different from these values.

When culture results and sensitivities are available, antibiotic choice can be tailored to a narrower spectrum for completion of therapy. If a child has a multidrug-resistant infection, the risk-benefit analysis may well favor the use of an antibiotic that does not have a favorable safety profile if no other alternative exists. In some critically ill children, combination antibiotic therapy may be warranted to augment the antibiotic killing capacity, increase tissue penetration, or prevent antibiotic resistance.

On the basis of the overall clinical assessment, supported by laboratory and imaging data and the response to empiric therapy, the physician needs to decide whether to continue therapy for a complete treatment course or stop the antibiotics if data do not support an infection as the cause of the child's clinical state. Optimal duration of antibiotic therapy for infections in the PICU is poorly defined; however, in specific situations, shorter duration of antibiotic use may reduce length of ICU stay, antibiotic resistance, and the emergence of secondary infections. Monitoring serum inflammatory markers may allow optimization of both the antibiotic regimen and duration of treatment.[10]

Antibiotic Classes

β-Lactam Antibiotics

β-Lactam antibiotics are a diverse group of antibiotics. The β-lactam ring that characterizes these compounds is usually attached to a ring structure that defines the class of antibiotic agents as penicillins, cephalosporins, carbapenems, or monobactams (Fig. 107.1). The β-lactam structure is thought to interfere with bacterial cell wall synthesis and repair by preventing transpeptidation and

transglycosylation of the pentapeptide precursors in the formation of peptidoglycan.[11] The target transpeptidase enzymes, also known as *penicillin-binding proteins* (PBPs), are vital for the maintenance of cell wall integrity. PBPs carried by different bacterial species have different structures, leading to differences in the binding affinity for various β-lactam agents. Long-term, high-dose use of all β-lactam agents may be associated with reversible neutropenia.

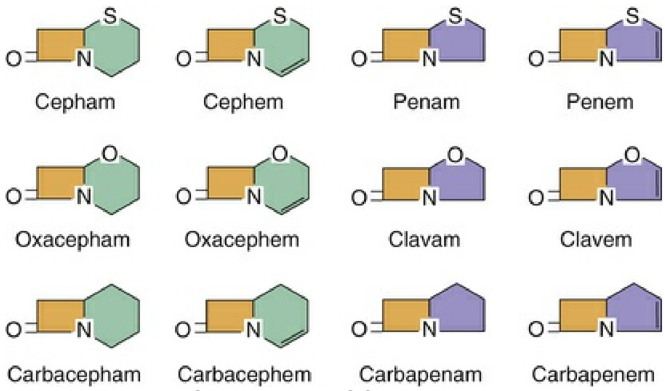

FIG. 107.1 Structures of β-lactam antibiotics.

Penicillins

Penicillins can be divided into groups that are based largely on spectrum of activity and chemistry. The natural penicillins, penicillin G and penicillin V, are active against a number of aerobic and anaerobic bacteria but are primarily used for the treatment of streptococcal (Group A and B streptococci) and spirochete infections, such as syphilis. The aminopenicillins, ampicillin and amoxicillin, have expanded activity against gram-negative organisms and are the agents of choice for susceptible enterococci. The penicillinase-resistant penicillins, oxacillin and nafcillin, are highly effective for the treatment of infections due to susceptible *Staphylococcus aureus*. Piperacillin is the only extended-spectrum penicillin currently available in the United States and only in fixed combination with the β-lactamase inhibitor, tazobactam. Piperacillin has enhanced activity against gram-negative organisms, including *Pseudomonas aeruginosa,* with reasonable gram-positive coverage, including *Enterococcus* spp.

β-Lactam Antimicrobial Plus β-Lactamase Inhibitor Combination

Ampicillin, amoxicillin, and piperacillin have been combined with a β-lactamase inhibitor that allows for enhanced gram-negative activity when compared with the β-lactam alone. The first β-lactam drug component, the actual antibiotic, effectively binds to the target site in the bacteria and results in the death of the organism. The second component, the *β-lactamase inhibitor,* has poor intrinsic activity as an antibiotic but may irreversibly bind to and neutralize the β-lactamase enzyme the organism has produced. The combination adds to the spectrum of the original antibiotic when the mechanism of resistance is a β-lactamase enzyme. The addition of sulbactam to ampicillin (Unasyn) and clavulanate to amoxicillin (Augmentin) expands the spectrum of activity to include *S. aureus, B. fragilis,* and many β-

lactamase producing gram-negative organisms. Similarly, the addition of tazobactam to piperacillin (Zosyn) results in enhanced anaerobic and gram-negative activity.

Cephalosporins

Cephalosporins can be distinguished on the basis of activity against gram-negative pathogens and stability of the antibiotic to a number of the gram-negative β-lactamases. The cephalosporins fall roughly into five "generations" on the basis of these characteristics. First-generation cephalosporins (cephalexin, cefazolin) are generally most active against some gram-positive pathogens such as *S. aureus,* with more limited gram-negative activity. Importantly, none of the current cephalosporin antibiotics of any generation display activity against the enterococci. The second-generation cephalosporins (cefuroxime) have increased intrinsic activity against gram-negative organisms, including *Escherichica coli* and *Klebsiella,* on the basis of enhanced stability against the organisms' principle β-lactamases. Activity against *S. aureus* is decreased compared with the first-generation cephalosporins but is sufficient to achieve clinical success in most situations. A slightly different group of antibiotics, the cephamycins (cefoxitin, cefotetan), have activity against the gram-negative enteric bacilli similar to the second-generation cephalosporins but display enhanced anaerobic activity against *B. fragilis* and may play a role in the treatment of intraabdominal infections. Their activity against *B. fragilis,* however, is inferior to metronidazole, clindamycin, or the carbapenems. The third-generation cephalosporins, cefotaxime and ceftriaxone, have enhanced stability against the most prevalent β-lactamases of *Haemophilus influenzae, E. coli,* and *Klebsiella* and enhanced activity against many of the Enterobacteriaceae but are, unfortunately, not stable to the inducible chromosomal β-lactamases (AmpC, type I) of *Enterobacter, Serratia,* or *Citrobacter*. Ceftazidime, another third-generation cephalosporin, has far greater intrinsic activity against *P. aeruginosa* than previous cephalosporins. None of the third-generation cephalosporins are as active against *S. aureus* as first- and second-generation agents. Cefepime, a fourth-generation cephalosporin, has the best overall activity against both gram-negative and gram-positive pathogens, with activity against *P. aeruginosa* equivalent to ceftazidime and activity against *S. aureus* equivalent to second-generation cephalosporins. It is also the most stable to β-lactamase degradation. The novel fifth-generation cephalosporin, ceftaroline, is the first β-lactam antibiotic with activity against methicillin-resistant *S. aureus* (MRSA) and has been approved for the treatment of adults with community-acquired pneumonia and skin and skin structure infections. In addition to its activity against MRSA, ceftaroline has a spectrum of gram-negative activity similar to that of third-generation cephalosporins.

Carbapenems

Three carbapenems, imipenem (combined with cilastin, an inhibitor of a renal tubular dehydropeptidase enzyme, to avoid nephrotoxicity), meropenem, and ertapenem, are currently FDA approved in children older than 3 years of age for the treatment of complicated skin and skin structure infections (SSIs), complicated intraabdominal infections, and meningitis. The carbapenems have a β-lactam ring structure that differs slightly from the penicillins and cephalosporins (see Fig. 107.1),

with chemical modifications to enhance activity and stability. The broad antimicrobial spectrum of activity of the carbapenems is similar and includes gram-negative, gram-positive, and anaerobic organisms. Given their spectrum of activity, carbapenems are generally reserved for nosocomial infections or those due to organisms for which there are few alternatives, such as extended-spectrum β-lactamase (ESBL) producing gram-negative organisms or those harboring a chromosomally mediated ampC β-lactamase, like *Enterobacter* spp.

With respect to toxicity, the carbapenems are well tolerated, although imipenem displays interference with central nervous system γ-aminobutyric acid inhibition of neuron activity and was shown to be associated with an increase in seizure activity in children treated for bacterial meningitis compared with historic controls.[12] On the basis of these observations, meropenem is the preferred carbapenem for children at risk for seizures or with central nervous system (CNS) infections and inflammation.

Monobactams

Aztreonam, the only monobactam currently available, has a unique chemical structure in which the β-lactam ring is not attached to an adjacent five- or six-membered ring but does have chemical additions to the β-lactam ring that enhance activity and stability to β-lactamases. It displays aerobic, gram-negative activity, including activity against many strains of *P. aeruginosa*.

Aminoglycosides

Aminoglycoside antibiotics are bactericidal in a concentration-dependent fashion against a wide range of aerobic pathogens. These agents inhibit protein synthesis by irreversible binding to the 30S ribosomal subunit. The gram-negative spectrum of activity is extensive, including enteric bacilli *(E. coli, Klebsiella, Enterobacter, Serratia), P. aeruginosa,* and many free-living gram-negative bacilli. These antibiotics have no clinically relevant anaerobic activity.

Although the first aminoglycosides exhibited substantial renal toxicity and ototoxicity, subsequent agents are significantly safer. The most widely available parenteral agents are gentamicin, tobramycin, and amikacin. Because of the relatively low serum concentrations necessary to prevent toxicity and poor penetration into the spinal fluid, these agents are not used as primary therapy of CNS infections. Caution should be exercised in the use of these agents in undrained abscess infections, including intraabdominal infections. The acidic and anaerobic conditions present in abscesses produce MICs against aerobic gram-negative organisms that are 10 times higher than those documented under ideal laboratory conditions.[13]

Aminoglycoside-induced nephrotoxicity has been described, even in non–critically ill children, and is associated with poorer outcomes.[14] As a result, the role of aminoglycosides as part of combination therapy for the treatment of gram-negative and gram-positive infections continues to evolve. The previously held notion that an aminoglycoside should be combined with a β-lactam to retard the development of resistance has been challenged by recent studies, including a propensity score–adjusted, retrospective cohort study of pediatric patients with gram-negative bacteremia that found no survival benefit with addition of an aminoglycoside to patients on a susceptible β-lactam agent.[15,16] It is also unclear whether the empiric

addition of an aminoglycoside is warranted for the management of gram-negative bacteremia while awaiting susceptibility results. A recent retrospective pediatric study found no survival benefit to empiric combination therapy, except for patients with risk factors for multidrug-resistant, gram-negative (MDRGN) infection: a history of previous colonization or infection with an MDRGN, broad-spectrum antibiotic therapy within 30 days, a prolonged current hospitalization, or a high prevalence of MDRGNs in the community.[16] The role of low-dose gentamicin as part of combination therapy for the management of uncomplicated *Enterococcus faecalis* bacteremia in children remains unresolved. A recent retrospective study found that while the addition of gentamicin decreased the time to bacterial clearance by 10 hours, there was no impact on bacteremic relapse, and the risk of developing acute kidney injury was twice as high.[17]

Glycopeptides

Vancomycin is currently the only available glycopeptide in the United States. The glycopeptides are primarily active against aerobic and anaerobic gram-positive organisms. Vancomycin is bactericidal against virtually all strains of staphylococci and against most strains of streptococci, although it is bacteriostatic against the enterococci. Resistance to vancomycin is noted to occur in strains of *Enterococcus faecium* (vancomycin-resistant enterococcus [VRE]) and has also been described in *S. aureus*.[18,19] This class of antibiotic is cell wall active, as are the penicillins, but has a different mechanism of action in prevention of pentapeptide cross-linking in the formation of cell wall peptidoglycan.

The tissue distribution of vancomycin is extensive, with elimination of unchanged antibiotic by the kidney. Dosage adjustment is required in renal insufficiency. Penetration into the cerebrospinal fluid (CSF) is not well studied and is erratic. Serum concentrations of approximately 40 μg/mL are thought to be necessary to achieve CSF concentrations sufficiently high enough to achieve a reliable microbiologic cure in meningitis or ventriculitis. The toxicities of vancomycin are primarily nephrotoxicity and ototoxicity. As with the aminoglycosides, close attention to serum antibiotic concentrations will mitigate clinically significant toxicity.

The new-generation lipoglycopeptides, dalbavancin, telavancin, and oritavancin, are FDA approved in adults for the treatment of complicated skin or skin structure infections caused by susceptible gram-positive organisms, including MRSA. Their role in the management of pediatric patients remains unsettled.

Macrolides

Erythromycin and the related macrolides, clarithromycin and azithromycin, may be required in the PICU for children with severe pertussis or atypical pneumonia or in children with extensive drug allergy precluding the use of standard antiinfective agents. The macrolides bind to the 50S ribosomal subunit of susceptible bacteria to prevent the formation of peptide chains, thereby inhibiting protein synthesis. In general, both clarithromycin and azithromycin are better tolerated than erythromycin because of the lack of degradation products seen with erythromycin that stimulate motilin receptors and lead to nausea, vomiting, and abdominal

cramps. Clarithromycin and azithromycin achieve high intracellular concentrations, with demonstrated efficacy against intracellular pathogens and all of the macrolides demonstrate activity against atypical bacteria, including *Mycoplasma pneumoniae, Chlamydia, Legionella,* and *Bordetella pertussis*. In addition, azithromycin has potential efficacy as a modulator of airway hyperresponsiveness,[20] even in the absence of overt infection,[21] that may have a role for children in the ICU with community-acquired pneumonia and exacerbation of underlying chronic lung disease or asthma. Macrolides are metabolized by cytochrome P-450 enzymes, which cause potential drug-drug interactions.

Fluoroquinolones

This class of broad-spectrum agents has been extremely successful in adults over the past 20 years. Because of concerns regarding cartilage toxicity in weight-bearing joints of experimental animals, however, pediatric studies have been limited. The mechanism of action of quinolones involves inhibition of DNA synthesis by interference with two bacterial enzymes. The activity of each specific quinolone and the rapidity of the development of resistance to the specific quinolone depend on the relative activity of the quinolone against these enzymes.[22]

Ciprofloxacin, the first of the agents approved for use in adults, shows outstanding activity against *P. aeruginosa,* as well as many enteric bacilli causing both nosocomial *(E. coli, Klebsiella, Enterobacter)* and gastrointestinal infections (*Salmonella, Shigella, Campylobacter, Yersinia,* and *Aeromonas*). Although resistance to ciprofloxacin in *P. aeruginosa* and other bacilli has been increasing, susceptibility in pediatric inpatient units has remained reasonable. Ciprofloxacin is FDA approved in children older than 1 year for the treatment of complicated urinary tract infections, pyelonephritis, and postexposure treatment of inhalational anthrax. Subsequent chemical modifications of fluoroquinolones have resulted in a set of agents with good to excellent activity against gram-positive cocci, including group A streptococcus, *S. pneumoniae,* and *S. aureus*. These agents—levofloxacin and moxifloxacin—are effective in both gram-positive and gram-negative infections. Although case reports of possible cartilage toxicity exist, no documented case unequivocally caused by fluoroquinolones in children has been published in any prospective study.[23]

Miscellaneous

Clindamycin

A member of the lincosamide family, clindamycin inhibits the growth of bacteria by binding to the 50S subunit of the ribosome. Clindamycin is active against gram-positive organisms and many anaerobes. Activity against β-lactam–resistant strains of *S. pneumoniae* and *S. aureus* (MRSA) has led to increased use of clindamycin in children.[24]

In children with infection caused by strains of *S. aureus* or group A streptococcus that are suspected to produce toxin-mediated disease (eg, toxic shock syndrome, necrotizing fasciitis), clindamycin is often used (in conjunction with a β-lactam agent) to stop toxin production as quickly as possible. Retrospectively collected data suggest improved outcomes in patients treated with the combination.[25] Clindamycin

may be used for treatment of MRSA skin infections and pneumonia; however, it is not recommended as the sole agent for critically ill patients with MRSA infections. Given its excellent gram-positive and anaerobic activity, clindamycin can also be used in the treatment of aspiration pneumonia and head and neck infections.

Linezolid

Linezolid is the first in a class of new antibiotics, the oxazolidinones. These antibiotics are protein synthesis inhibitors that interfere with mRNA binding at the 30S ribosome subunit. Linezolid is a bacteriostatic agent useful in the treatment of infections caused by gram-positive organisms, including MRSA, coagulase-negative staphylococci, and VRE. Linezolid has been studied and has received FDA approval for use in pediatric patients, including the neonatal age group. Linezolid is approved for the treatment of community- and hospital-acquired pneumonia, complicated and uncomplicated skin and soft tissue infections, and bacteremia caused by vancomycin-resistant organisms.

A concern that appears to have little clinical relevance in healthy children treated under controlled conditions is the drug's nonselective, reversible inhibition of monamine oxidase. Nevertheless, this drug interaction profile has potential impact on the patient in the PICU who is receiving adrenergic or serotonergic drugs. Linezolid has been reported to be associated with hematologic side effects and rarely with optic neuritis and peripheral neuropathy.

Metronidazole

A nitroimidazole derivative, metronidazole is an effective antibiotic for parasitic and anaerobic bacterial infections. The primary use of metronidazole in the PICU includes infections caused by β-lactamase–positive strains of *B. fragilis* (intraabdominal infections) and those caused by *C. difficile* (pseudomembranous colitis). Resistance to metronidazole has not been a clinical problem despite significant clinical use. The distribution of drug in tissues is extensive, including CNS penetration. It has been a standard component of therapy for anaerobic deep tissue space infections and has been used in the treatment of anaerobic brain abscesses. It remains the agent of choice (by the oral route, if possible) for the therapy of *C. difficile* infection.

Colistin

With antibiotic resistance increasing dramatically in gram-negative pathogens, colistin has returned to clinical use and now represents a therapy of last resort for organisms resistant to all other available antibiotic therapy.[26] Colistin (colistimethate), or polymyxin E, has broad-spectrum bactericidal activity against gram-negative organisms by acting as a cationic detergent, destroying the bacterial cytoplasmic membrane. Colistin has no activity against gram-positive organisms or against *B. fragilis*. The chief toxicities of this agent include nephrotoxicity, peripheral neuropathy, confusion, coma, and seizure. The drug is renal eliminated, and dosage adjustment is required with renal insufficiency. Limited data in pediatric burn and critical care patients suggest colistin is effective and safe for multidrug-resistant gram-negative infections.[27,28] In addition, aerosolized colistin has been used as an adjunctive or monotherapy for gram-negative pulmonary infections. Clinically

significant bronchospasm may occur.

Tigecycline

Tigecycline is the first in a new class of antibiotics, the glycylcyclines. Tigecycline inhibits protein synthesis and is generally considered a bacteriostatic agent. It has broad-spectrum antibacterial activity against gram-positive and gram-negative aerobes and anaerobes, including MRSA and multidrug-resistant gram-negative bacteria. It is not effective against *Pseudomonas, Providencia,* and *Proteus* species. Tigecycline is approved for use in adult patients with complicated skin and SSIs, complicated intraabdominal infections, and community-acquired pneumonia. The role of tigecycline in the pediatric population has yet to be defined.

Daptomycin

Daptomycin belongs to a new class of antibiotics, the lipopeptides. Daptomycin disrupts the cell membrane and is rapidly bactericidal. It has a broad range of activity against gram-positive bacteria including methicillin, vancomycin, and linezolid-resistant organisms. It should not be used to treat pulmonary infections because surfactant inhibits its activity. Daptomycin is currently approved for use in adults with complicated skin and skin structure infections, as well as right-sided endocarditis and staphylococcal bacteremia. A recent review of daptomycin therapy in invasive gram-positive infections in children showed its addition to the treatment regimen resulted in bacteriologic cure in six of seven patients with persistent bacteremia and was well tolerated.[29] The primary toxicity seen is a dose-dependent, reversible myopathy that can be monitored by elevation in serum creatinine phosphokinase.

Fungal Infections and Antifungal Agents

Invasive fungal infections are increasingly recognized as a significant risk among immunocompromised and critically ill children.[30] Indeed, *Candida* species are the third most common cause of health care–acquired bloodstream infection in the United States, following coagulase-negative staphylococci and enterococci.[31] As they are also associated with excessive morbidity and mortality, a basic understanding of the epidemiology, diagnosis, and management of invasive fungal infections is essential.

Candida

Although epidemiologic data are sparse, recent studies suggest that around 8% of all hospital-acquired bloodstream infections in the United States are due to *Candida* spp. Candidemia is associated with a high rate of morbidity and mortality among children in the PICU. The 30-day mortality rate for children in the PICU with candidemia may be as high as 37% to 44%, and a multivariate analysis of children with invasive candidemia at a large, tertiary children's hospital found that location in the PICU at the time of diagnosis and the presence of an arterial catheter were the only two independent risk factors for death.[32] General risk factors for the development of *Candida* central line–associated bloodstream infections among pediatric patients include intestinal failure, presence of a gastrostomy tube, and

receipt of total parenteral nutrition or blood transfusions.[33] Factors specifically associated with the development of candidemia for children in the PICU include presence of a central venous catheter, a diagnosis of malignancy, and receipt of either vancomycin or antimicrobials with activity against anaerobic organisms for more than 3 days.[32]

There are many candida species, each with their own unique pathogenicity and susceptibility. *C. albicans* and *C. parapsilosis* remain the most common pathogens identified, although the incidence of infection due to other species (eg, *C. glabrata, C. tropicalis, C. krusei*) is rising.[33] Blood culture remains the gold standard for the diagnosis of invasive candidiasis, although its sensitivity will vary depending on the extent of infection and particular *Candida* species. For example, cultures may be negative in patients with deep-seated candidiasis without concomitant candidemia.[34] Although several nonculture diagnostics, including β-D-glucan detection and serum polymerase chain reaction (PCR), have been developed to aid in the diagnosis of invasive candidiasis, their use has not been validated in children and further studies are necessary before their routine use can be recommended.

Aspergillus and Other Invasive Molds

Aspergillus species are responsible for the majority of invasive mold infections among children, and the increased incidence of invasive aspergillosis has paralleled the survival of children with immunocompromising conditions.[35] Infection is most commonly due to members of the *A. fumigatus* species complex, although certain conditions are associated with more unusual species (eg, *A. nidulans* in patients with chronic granulomatous disease).[36] Invasive aspergillosis is associated with compromised immune function and is associated with prolonged or repeatedly profound periods of neutropenia. High-risk populations include children with hematologic malignancies (particularly children with acute myelogenous leukemia [AML] or high-risk acute lymphoblastic leukemia [ALL]), hematopoietic stem cell transplant recipients (particularly in the setting of graft-versus-host disease), solid organ transplant recipients, patients with a primary immunodeficiency, and neonates.[36,37]

The lung is the most common site of invasive aspergillosis, although the spectrum of disease includes sinopulmonary, gastrointestinal, cutaneous, and CNS infection. Symptoms are often nonspecific, including fever, cough, dyspnea, and chest pain, so vigilance for potential infection in vulnerable populations is critical. Occult fungal infection should be considered in any patient with chemotherapy-induced neutropenia with fever persisting more than 96 hours, despite empiric antibiotic therapy.[38] The diagnosis of invasive mold infections is challenging, and culture remains the gold standard for the determination of species identification and antifungal susceptibility.[39] As with the diagnosis of invasive candidiasis, noninvasive diagnostic methodologies including serum aspergillus galactomannan antigen, β-D-glucan, and PCR detection of *Aspergillus* spp. have been developed, although data regarding their utility in children are mixed. While the galactomannan antigen is relatively specific for *Aspergillus* spp., it does cross-react with other fungi, including *Histoplasma capsulatum* and *Cryptococcus neoformans,* and is less sensitive in non-neutropenic hosts.[40] The estimated sensitivity and specificity of serum galactomannan testing for the diagnosis of invasive aspergillosis in children are 76% and 86%. Serial screening of serum galactomannan in at-risk children may help

make the diagnosis of invasive aspergillosis sooner and is endorsed by European guidelines.[41] Galactomannan can also be detected in bronchoalveolar lavage fluid and may be helpful in the diagnosis of pulmonary aspergillosis.[42] Imaging can also be useful in diagnosing and determining the extent of invasive aspergillosis, although classic chest CT findings, such as the halo sign, air crescent sign, and cavitation, may be less common in children.[41]

There are a number of other potential invasive mold infections encountered in the pediatric population, although a complete discussion is beyond the scope of this chapter. It is important to note that given the unique pathogenicity and susceptibility of each organism, a microbiologically confirmed diagnosis is critical to the successful management of any invasive mold infection.

Antifungal Agents

There are four major classes of antifungals used for the treatment of invasive fungal infection, including the polyenes (amphotericin and its liposomal derivatives); triazoles (fluconazole, itraconazole, voriconazole, and posaconazole); echinocandins (micafungin, caspofungin, and anidulafungin); and the pyrimidine analog, flucytosine (Table 107.3).

TABLE 107.3

Activity of Selected Antifungal Drugs

Organism	Fluconazole	Voriconazole	Posaconazole	Amphotericin	Echinocandin
Candida albicans	+	+	+	+	+
Candida glabrata	±	+	+	+	+
Candida krusei	−	+	+	+	+
Candida lusitaniae	+	+	+	−	+
Candida parapsilosis	+	+	+	+	±
Blastomyces dermatitidis	+	+	+	+	−
Coccidioides immitis	+	+	+	+	−
Histoplasma capsulatum	+	+	+	+	−
Cryptococcus	+	+	+	+	−
Aspergillus fumigatus	−	+	+	+	+
Aspergillus terreus	−	+	+	−	+
Mucorales	−	−	+	+	−
Fusarium	−	+	+	+	−
Scedosporium	−	±	±	−	−

Amphotericin

One of the first antifungal agents developed, amphotericin B deoxycholate, remains an important member of the intensivist's antifungal armamentarium. Amphotericin is broadly fungicidal against most yeast, molds, and dimorphic fungi. It exerts its effect by binding to fungal cell membrane ergosterols, resulting in increased cell permeability, leakage of intracellular contents, and concentration-dependent cell death.[43] Owing to its poor bioavailability, amphotericin B is generally given parenterally, although nebulized amphotericin has also been used in the treatment of *Aspergillus* lung infections.[44] Upon entering the bloodstream, the drug distributes widely into tissues, particularly organs of the reticuloendothelial system. Although CNS penetration is poor, the agent has been used extensively for the management of such infections and remains the drug of choice for induction therapy in patients with cryptococcal meningoencephalitis.[45] On the basis of concerns that liposomal

amphotericin may fail to adequately penetrate renal tissue and the urinary tract, amphotericin B deoxycholate remains the preferred amphotericin product for both urinary tract and neonatal candidiasis.[46]

As its ergosterol target is similar to human cholesterol, amphotericin B deoxycholate is associated with significant side effects, including nephrotoxicity, electrolyte wasting, fever, chills, and hematologic effects.[47] To combat these effects, various lipid formulations of amphotericin B have been developed. While amphotericin B deoxycholate and its liposomal derivatives are generally equivalent in terms of clinical efficacy, conventional amphotericin is significantly more potent and dosing between agents is not interchangeable.[48] Renal toxicity is mitigated by the use of lipid-based formulations of amphotericin B, although significant electrolyte disturbances, including hypomagnesaemia and hypokalemia, remain common. The most common side effects are related to infusion of the drug (fever, rigors, nausea, vomiting). Slow infusion and premedication with acetaminophen and diphenhydramine may help prevent or minimize such reactions.

The most commonly used liposomal formulation of amphotericin in pediatrics, amphotericin B liposome, is FDA approved for the treatment of invasive aspergillosis, candidiasis, cryptococcal meningitis, cryptococcosis, and visceral leishmaniasis in children. It is also approved for the treatment of presumed fungal infection in febrile, neutropenic patients and remains the drug of choice for treatment of infections due to the *Mucorales,* including *Rhizomucor* spp., *Rhizopus* spp., and *Mucor* spp. Pathogens for which amphotericin is less reliably effective include *A. terreus, C. lusitanea,* members of the genus *Scedosporium, Trichosporon* spp., and *Fusarium* spp.[49-52]

Triazoles

The triazoles fluconazole, itraconazole, voriconazole, and posaconazole are generally well tolerated and demonstrate activity against a number of fungal species. The triazoles disrupt the synthesis of ergosterol, a critical component of the fungal cell membrane, which results in inhibition of cell growth and replication. Fluconazole has greatest activity for yeast and is fungistatic for most *Candida* species, with the exception of *C. krusei* and *C. glabrata,* which are generally resistant.[53] Importantly, fluconazole lacks fungicidal activity against molds, including *Aspergillus* spp. Fluconazole has excellent bioavailability and concentrates in the urine, making it an excellent choice for susceptible genitourinary infections.[46] Itraconazole is available in oral formulation only and, given its erratic pharmacokinetics and the existence of alternative agents, is generally reserved for the treatment of endemic mycoses. Voriconazole is available in both parenteral and enteral formulations and remains the drug of choice for invasive aspergillosis. To improve solubility, the parenteral formulation of voriconazole includes a cyclodextrin carrier molecule, which is cleared by glomerular filtration. Accumulation of this molecule has been associated with hepatotoxicity and nephrotoxicity in animal studies, and the oral formulation is therefore preferred for patients with a creatinine clearance less than 50 mL/min.[54] Due to genetic polymorphism of CYT P-450 and CYP2C19, voriconazole is associated with considerable interpatient and intrapatient drug level variability and, as such, drug level monitoring is advised when treating patients with invasive aspergillosis. Available data suggest that trough concentrations of 1 to 5.5 μg/mL should be targeted.[55] Posaconazole is unique among the triazoles in its activity against

mucormycoses, although its role in the management of children with invasive fungal infection remains to be elucidated.

The triazole drugs are relatively well tolerated and have a more favorable side effect profile than amphotericin B. Fluconazole is a potent inhibitor of CYP2CP and CYP3A4, resulting in the potential for significant drug-drug interactions. Serious treatment-related adverse events related to fluconazole use are rare. Voriconazole has been associated with a number of side effects, including photosensitivity rash, transaminase elevation, visual changes, and periostitis. Members of the azole class have the potential to prolong the QT interval and have been associated with torsades de pointes.[56]

Echinocandins

The echinocandins caspofungin, micafungin, and anidulafungin are structurally similar compounds that work by disrupting the synthesis of 1,3-β-glucan, a polysaccharide component of the fungal cell wall.[57] All three of the available echinocandins offer a similar spectrum of activity and are available only in parenteral form. These agents are fungicidal against most *Candida* spp., fungistatic against molds, like *Aspergillus* spp., and have been shown to have potent in vitro activity against candidal biofilms present on foreign bodies, such as indwelling devices and prostheses.[58] Although *C. parapsilosis* has an intrinsically higher MIC to echinocandins, one recent study found that the initial use of these agents was not associated with clinical failure in patients with *C. parapsilosis* candidemia.[59] Data suggest that the echinocandins are noninferior to, and possibly more efficacious than, fluconazole for the treatment of candidemia and other forms of invasive candidiasis in adults.[60] In fact, a recent patient-level review of randomized trials for the treatment of invasive candidiasis identified receipt of an echinocandin and removal of the central venous catheter as the only two factors associated with improved survival.[61] On the basis of their activity and the emergence of azole-resistant *Candida* species, current clinical practice guidelines suggest that an echinocandin be considered as first-line therapy for neutropenic patients with confirmed or suspected candidemia and for the treatment of candidemia in non-neutropenic hosts with recent azole exposure, whose illness is moderately severe or severe, or who are at high risk of infection due to *C. glabrata* or *C. krusei*.[46] Although not recommended as first-line therapy, caspofungin is FDA approved as salvage treatment for invasive aspergillosis, and there are some clinical data suggesting benefit when used in combination with voriconazole as part of the initial treatment of invasive aspergillosis.[62-64] Importantly, the echinocandins have poor CNS and ocular penetration and should generally be avoided for infections of these spaces. The echinocandins are generally well tolerated, although liver enzyme elevation is occasionally encountered.

Flucytosine

Flucytosine is a pyrimidine analog that interferes with protein synthesis by incorporation into fungal RNA after being converted to 5-FU intracellularly. It is rarely used in pediatrics, owing to its narrow therapeutic index, and is generally reserved as part of combination therapy with amphotericin B for patients with cryptococcal meningitis.[45]

There are few indications for combination antifungal therapy. As previously stated, there may be a benefit to the addition of an echinocandin to voriconazole, particularly in the initial phase of treatment, for patients with invasive aspergillosis. Due to its highly unpredictable susceptibility, it is prudent to treat documented infections due to *Fusarium* spp. with either voriconazole or posaconazole and an amphotericin product while awaiting sensitivities. If *Mucorales* infection is being considered, the addition of an amphotericin product to ongoing triazole therapy is rational.

Antibiotic Resistance

Antibiotic-Resistance Mechanisms

In the ICU, antibiotic use is extensive, resulting in selective pressure for antibiotic-resistant pathogens. Bacteria are capable of surviving in an environment containing antibiotics by the expression of one or more of many different potential antibiotic-resistance mechanisms. The basic mechanisms of resistance can be divided into two broad categories.[65,66] The first is by accumulation of multiple genes, each coding for resistance, that occur typically on resistance (R) plasmids and include (1) alteration of the antibiotic structure by bacterial enzymes, (2) alteration of the antibiotic's target site within the pathogen (by mutation at the binding site or enzymatic alterations of the binding site), or (3) changes in the cell wall that prevent movement of the antibiotic into the organism. The second resistance mechanism occurs by extrusion of the antibiotic from within the organism by efflux pumps. Although community-acquired pathogens most often express only one mechanism of resistance, nosocomial pathogens may express many of these mechanisms simultaneously, and the result is a high degree of antibiotic resistance. In addition, the regulation of resistance gene expression may be altered to allow increased production of the gene product that leads to resistance.

Genes encoding antibiotic resistance may be shared between organisms within a species or between species. The transfer of antibiotic resistance genes by plasmids is a common method by which resistance is shared between bacteria. The description of mobile genetic elements helps explain the rapid development and spread of antibiotic resistance within the pathogens responsible for nosocomial infections.[67] Antibiotic-resistant mutants normally exist at low frequencies in any given population of bacteria. Antibiotic exposure is often the selection pressure allowing these otherwise silent mutants to achieve significant numbers, leading to treatment failure. The clinical expression of antibiotic resistance may involve several different mechanisms operating simultaneously within a pathogen, with each mechanism expressed to a different degree on the basis of the regulation of resistance at a molecular level.

Antibiotic Resistance and Infections in the Pediatric Intensive Care Unit

Current clinical challenges relate to pathogens that display newer resistance patterns. Some ESBL-producing gram-negative pathogens are resistant to extended-

spectrum penicillins, as well as third- and fourth-generation cephalosporins, with a proportion of these organisms also demonstrating decreased susceptibility to aminoglycosides, carbapenems, and fluoroquinolones. Outbreaks caused by ESBL-producing *Klebsiella* and *E. coli* have been widely reported.[68] Outbreaks by enteric gram-negative bacilli that carry chromosomal AmpC β-lactamases (present in *Enterobacter, Serratia,* and *Citrobacter*) have been occurring for several years and continue to present challenges.[69] *P. aeruginosa* has always been a nosocomial problem in neonatal ICUs and PICUs.[70] The nonfermenting gram-negative bacteria, including *Stenotrophomonas* and *Acinetobacter* spp., may also cause antibiotic-resistant organism infections, particularly in the immunocompromised child.

Community-acquired MRSA is increasingly a significant pathogen in children.[71] MRSA develops resistance via the mecA gene and detection of the gene predicts failure of treatment with oxacillin. VRE strains have been reported in pediatric hospitals, particularly in neonatal ICUs, in oncology wards, and in patients with gastrointestinal disease. The vancomycin resistance strains have a complex resistance mechanism including six different phenotypes and production of a carboxypeptidese.[18,72]

Antibiotic Therapy for Resistant Pathogens

MRSA is a frequently isolated nosocomial and community-acquired pathogen in PICUs. Almost 60% of catheter-related bloodstream infections in the PICU are caused by gram-positive bacteria.[73] Vancomycin remains the mainstay of treatment for serious MRSA infections. Some data in the adult population suggest that the use of high-dose vancomycin (target serum concentration/minimum inhibitory concentration of ≥400 μg/mL) is associated with favorable clinical outcomes. Few pediatric clinical trials have looked at the question of whether alternative antibiotics are superior to vancomycin for MRSA. A pediatric study compared vancomycin with linezolid for the treatment of nosocomial pneumonia, bacteremia, or skin and soft tissue infections; the cure rates were similar.[74] Other newer agents, including daptomycin and ceftaroline, are available, but experience in pediatrics is limited.

The incidence of vancomycin-resistant enterococcal infections is increasing and has been reported to be as high as 75% for *E. faecium* in adult ICUs. Linezolid is a mainstay of treatment; however, resistance to linezolid has been reported. Daptomycin and tigecycline both have excellent activity against VRE, although there is limited pediatric experience to date. A review of pediatric patients with multidrug-resistant gram-positive infection showed that the addition of daptomycin to the treatment regimen resulted in clinical improvement in the majority of patients, and in six of seven patients with persistent bacteremia it resulted in bacteriologic cure.[29]

S. pneumoniae has developed increasing resistance to β-lactam antibiotics, macrolides, and trimethoprim-sulfamethoxazole. For children with suspected pneumococcal meningitis or other life-threatening pneumococcal infections, the addition of vancomycin to either ceftriaxone or cefotaxime has been the standard of care until susceptibility data are available and therapy can be narrowed if appropriate. Other options for therapy of non-CNS infections caused by resistant strains include a newer-generation fluoroquinolone or linezolid.

Antibiotic resistance is increasing in gram-negative organisms. These organisms

include ESBL-producing enteric gram-negative bacteria (*Enterobacter, Serratia,* and *Citrobacter*) and multidrug-resistant *Pseudomonas, Stenotrophomonas,* and *Acinetobacter*. Treatment for patients potentially infected with these organisms should be guided by local resistance patterns and antibiograms. Extended- or continuous-infusion dosing strategies with β-lactams such as Zosyn, cefepime, or meropenem for treatment of susceptible *Pseudomonas* strains in critically ill patients optimizes bactericidal exposure[75] and have been associated with improved outcomes.[76] Colistin is also an option for multidrug-resistant gram-negative infections.

Antimicrobial Stewardship

Antibiotic resistance is a challenge in the ICU setting, where there is a constant struggle to maintain balance between appropriate treatment of known life-threatening infection and broad empiric coverage of possible life-threatening infection. Principles have been established and stewardship guidelines for optimizing antimicrobial therapy have been published by a number of organizations, including the Infectious Diseases Society of America, Centers for Disease Control and Prevention, and World Health Organization. It is essential for hospitals to implement oversight and accountability over antimicrobial use as a matter of patient safety. Two broad interventional strategies for antimicrobial stewardship programs (ASPs) exist. One is the prospective audit and feedback program whereby ongoing review of antibiotic utilization and recommendations for adjustments are made to providers. A second strategy uses preauthorization in which antimicrobials are restricted by the institution and must be justified and approved at the time of use. Many ASPs are a blend of both strategies with an integration of supplemental programs such as formulary interventions, dose optimization, educational efforts, computer-assisted decision support, and adaptation of local published guidelines.[77]

With the move toward computerized provider order entry as the standard of care, there are ways to leverage computerized decision support for appropriate antimicrobial selection on the basis of diagnosis and local susceptibility profiles and dose optimization integrating patient characteristics such as renal function, allergies, and potential drug interactions while preserving clinical judgment and physician autonomy.

Ideally, outcomes should be measured such as antimicrobial consumption (days of therapy per 1000 patient days) or antimicrobial days of therapy to assess safety and cost effectiveness of ASPs. The ICU is an ideal environment for implementation of antimicrobial stewardship because of the intense use of antimicrobials and existence of significant drug resistance.

Summary

As medical care becomes more sophisticated and children with critical illness are hospitalized for longer periods receiving specialty or invasive therapies, the risk of development of complicated infections caused by multidrug-resistant pathogens increases. The physician is constantly being challenged to deliver effective

antimicrobial therapy, while at the same time preventing the selection of resistance. Knowledge of the pathogens most likely to be present and the potential resistance mechanisms in these organisms is important in selecting empiric antimicrobial therapy. An appropriate collection of cultures to obtain susceptibility information on the pathogens is crucial to optimize subsequent therapy and minimize resistance.

CHAPTER 108

Life-Threatening Viral Diseases and Their Treatment

Surabhi B. Vora, Alpana Waghmare, Danielle M. Zerr, Ann J. Melvin

PEARLS

- An astute clinician will obtain serum to store for future serologic testing when viral pathogens are considered as the potential cause of a critical illness.
- Diagnostic sensitivity is generally enhanced when samples for viral culture and staining are sent as early as possible in the course of illness.
- In general, current treatment for most viral infections is supportive with antiviral therapy generally limited to herpes viruses.
- When herpes simplex virus encephalitis or neonatal disease is suspected, empiric treatment with acyclovir must be rapidly initiated.
- Parainfluenza and influenza viruses are often associated with bacterial coinfections.
- To prevent spread of infection to staff and other patients, appropriate infection control precautions should be initiated early when viral pathogens are suspected.

Viral infections are a frequent cause of disease in individuals of all ages. In general, the spectrum of illness is varied; young or immunosuppressed children are at higher risk of having severe disease. This chapter discusses viral illnesses commonly seen in the intensive care unit: myocarditis, hepatitis, pneumonitis, and meningitis/encephalitis. The content provides the reader with guidance for the initial management of patients infected with viral pathogens, with a particular emphasis on diagnosis and therapy.

Myocarditis

Background

Myocarditis accounts for approximately 0.05% of pediatric hospital discharges in the United States.[1,2] Although many infectious and noninfectious causes have been identified, viruses account for most cases.[3] The spectrum of disease is varied, and myocardial involvement may be focal or diffuse.[4] Thus establishing a definitive diagnosis can be difficult, and as a result, the true incidence of viral myocarditis is unknown.

Pathogenesis

Although the pathogenesis of viral myocarditis is not well understood, viruses appear to enter cardiac myocytes through specific receptors, and myocardial damage is thought to occur, at least in part, as a direct result of infection, with active viral replication leading to myocardial necrosis.[5] In addition, both humoral and cellular immune responses contribute to the pathogenesis of myocarditis,[6] through postinfectious autoimmune processes,[7] cytotoxic T lymphocytes, antibody-dependent cell-mediated cytotoxicity,[8] and cytokines.[9] With persistent viremia and the accompanying immune response, progression to dilated cardiomyopathy may occur.[10] Up to 27% of dilated cardiomyopathy in children may be attributable to viral myocarditis.[11]

Etiology

Polymerase chain reaction (PCR) of cardiac tissue from endomyocardial biopsy specimens in 34 children with a clinical diagnosis of myocarditis identified adenovirus in 44%, enterovirus in 24%, and herpes simplex virus (HSV) in 6%.[12] A shift has been noted toward parvovirus B19 and parechovirus.[4] Many other viruses have caused myocarditis in children, including influenza A, human immunodeficiency virus (HIV), cytomegalovirus (CMV), respiratory syncytial virus (RSV), and the mumps and measles viruses, before the widespread use of the measles-mumps-rubella (MMR) vaccine (Table 108.1).

TABLE 108.1

Viral Etiologies of Myocarditis, Fulminant Hepatitis, Pneumonia, Meningitis, Encephalitis, and Myelitis

	Myocarditis	Liver Failure	Pneumonia	Meningitis	Encephalitis	Myelitis

[1]Primarily in immunocompromised hosts.

[2]Primarily neonates and young infants.

[3]Viruses detected in myocardial biopsies appear to have shifted over the past few decades. (Cooper LT Jr. Myocarditis. N Engl J Med. 2009;360:1526-1538.)

XXX, Most frequent; *XX*, frequent; *X*, less common or rare.

Clinical Presentation

The clinical presentation of myocarditis can range from asymptomatic to acute fulminant disease with cardiovascular collapse. Infants with myocarditis may have nonspecific symptoms including poor feeding, fever, apnea, and listlessness. Physical findings may be consistent with congestive heart failure. Enteroviral myocarditis in infancy frequently occurs in conjunction with hepatitis or pneumonitis[13] and can be difficult to distinguish from bacterial sepsis. Severe dysrhythmias have been described in infants with myocardial involvement from RSV.[14] Older children and adolescents are more likely to present after a prodromal viral illness with nonspecific respiratory or gastrointestinal symptoms, usually without chest pain or cardiac symptoms, and thus diagnosis is often delayed.[15] Resting tachycardia disproportionate to the height of fever is common, and an apical systolic murmur may be heard. A subset of patients have fulminant myocarditis, characterized by rapid onset of symptoms, severe hemodynamic compromise, and fever.[16] Myocarditis has also been implicated in cases of sudden death.[17,18]

Laboratory abnormalities may include elevated white blood cell count, erythrocyte sedimentation rate,[19] and serum aspartate aminotransferase (AST) levels.[15,20] Cardiac troponin I and T are measures of cardiac muscle injury, which may be useful in myocarditis. Sensitivity of cardiac troponin T in children with myocarditis ranges from 71% to 100% with a specificity of 85% to 86%.[10,21,22]

Acute Liver Failure

Background

Acute liver failure (ALF) in children is defined as severe impairment of liver function with or without encephalopathy that occurs in a child with no history of chronic liver disease.[23] The causes of ALF in children can be metabolic, toxic, drug related, immune mediated, or infectious. The percentage of ALF caused by viral infections varies significantly by age and geographic location, with viral causes identified in 6% to 20% of pediatric ALF in series from North America and Europe[23-25] but 50% to 60% in other regions.[26-28]

Etiology

Although less than 1% of infections due to hepatitis A and B (HAV and HAB, respectively) result in ALF, these viruses constitute the majority of cases of ALF with a definitive viral diagnosis.[26,28-30] Although most perinatally acquired infections with HBV are asymptomatic, infants born to women with both hepatitis B surface antigen (HBsAg) and anti-hepatitis B envelope antibody (HBeAb) appear to be at risk for ALF.[31] Although rare, there are case reports of ALF with both postnatally and perinatally acquired hepatitis C virus (HCV) in children.[24,32,33] Other viruses identified in several pediatric series of ALF include adenovirus, CMV, enterovirus, HSV, Epstein-Barr virus (EBV), human herpesvirus 6 (HHV-6), parvovirus B19,[23-25,34] varicella-zoster virus (VZV),[35,36] influenza,[37,38] and hepatitis E, an enterically transmitted virus that causes epidemic hepatitis in many areas of the world, particularly in Asia.[39,40] ALF can also occur in severe dengue[41] and yellow fever infections[42]; though uncommon in the United States, these entities should be considered with the appropriate epidemiologic risk factors.

ALF in infants is most likely to be associated with systemic illness due to enterovirus, echovirus, HSV, or CMV.[23,30,43-46] Immune suppression is a risk factor for HSV-, CMV-, adenovirus-, and VZV-associated ALF.

Clinical Presentation

Symptoms of acute hepatitis include jaundice, anorexia, fatigue, nausea, and vomiting.[23,47] In fulminant disease, there is rapid progression to hepatic failure and encephalopathy. Physical examination may demonstrate fever, hepatosplenomegaly with liver tenderness, scleral or cutaneous icterus, and mucosal bleeding. Patients with severe vomiting may have significant dehydration. Laboratory studies include elevated hepatic enzymes (10- to 100-fold increases in aspartate aminotransferase [AST] and alanine aminotransferase [ALT]), hyperbilirubinemia, prolonged prothrombin time, and elevated ammonia levels. As hepatocyte necrosis progresses, hepatic enzyme levels may decrease and hepatomegaly may resolve. Renal failure is a common complication of ALF,[47,48] whereas cerebral edema is commonly found in the subset of patients with severe encephalopathy.[23,47]

Viral Pneumonia/Pneumonitis

Background

Influenza and pneumonia combined are a leading cause of death globally. A greater

burden of disease is present in infants, young children, and older individuals.[49] Although associated with only 20% to 50% of community-acquired pneumonias in adults,[50-52] viruses account for the majority of lower respiratory infections in children. In 2010, 14.9 million episodes of severe, acute lower respiratory infection (ALRI) resulted in hospital admissions in children <5 years worldwide.[53] In the United States, the annual incidence of pneumonia is estimated to be 15.7 cases per 10,000 children, with the highest rate among children <2 years of age (62.2 cases per 10,000 children) with an estimated 66% of these hospitalizations attributable to viral etiologies.[54]

Etiology

The etiologic agents of viral pneumonia are varied (see Table 108.1). RSV is the primary cause of hospitalization for respiratory tract illness in young children.[55] In a national surveillance study, most children with RSV infection had no coexisting medical conditions or characteristics that identified them as being at significantly greater risk for severe RSV disease, except for being <2 years of age.[55] Repeat infections are common. In the healthy host, infections are localized to the upper respiratory tract. Among immunocompromised patients, however, RSV infections can progress to fatal pneumonia, with the greatest mortality risk in patients with severe lower tract disease and in those who do not receive treatment.[56,57]

Influenza epidemics occur annually with significant morbidity and death in young children and older individuals. The highest rate of hospitalization occurs in the 0 to 5-month age group.[58] Since 2004, the total annual number of reported pediatric influenza deaths has ranged from 37 to 358, peaking with the 2009 H1N1 pandemic.[59] Among immunocompromised patients, risk factors for more severe disease include lymphopenia and infection early after hematopoietic stem cell transplant.[60] These patients have more complications, longer viral shedding, and more antiviral resistance while demonstrating fewer clinical symptoms and signs.[61]

In 2009, the emergence of a pandemic H1N1 strain of influenza A led to a greatly increased burden of influenza disease worldwide. Unlike seasonal influenza, children and young adults were at a disproportionate risk for infection and hospitalization; 60% of infections occurred in those <18 years of age.[62-64] The 2009 pandemic H1N1 strain continues to circulate with seasonal influenza globally.

Parainfluenza viruses (PIVs) are also significant causes of lower respiratory infection in children and immunocompromised patients.[65-68] PIVs account for 50% of hospitalizations for acute laryngotracheitis (croup) and at least 15% of cases of bronchiolitis and pneumonia. PIV types 1 and 2 cause more cases of croup, whereas PIV type 3 is more likely to infect the small air passages and cause pneumonia or bronchiolitis. However, any PIV can cause lower respiratory tract disease, particularly during primary infection or in immunocompromised hosts. In the latter, PIV pneumonia has a 30-day attributable mortality rate of >30%.[67,69,70] Unlike RSV, copathogens may be identified with PIV pneumonia more than 50% of the time[67]; therefore in high-risk patients, management should include workup and treatment for these other agents.

Other respiratory viruses that can cause pneumonia, particularly in young children and immunocompromised hosts, include human metapneumovirus (HMPV), adenovirus, human rhinoviruses (HRVs), and human coronaviruses

(HCoVs). Since it was first described in 2001,[71] HMPV has been shown to be a common cause of croup, bronchiolitis, and pneumonia in children, the elderly, and immunocompromised patients.[72-80] The clinical manifestations of HMPV are indistinguishable from RSV. Adenovirus pneumonia can occur as an isolated event or as part of disseminated disease. Risk factors for adenovirus pneumonia include compromised immune function, chronic underlying respiratory or cardiac disease, and age <7 years.[54,81] HRVs occasionally cause lower respiratory tract disease requiring admission to intensive care among pediatric and immunosuppressed patients, although a causative role is sometimes difficult to define because HRVs frequently occur in association with copathogens.[82-87] Among pediatric patients, a new species of rhinovirus (HRV-C) has been discovered that may cause more severe disease than HRV-A or HRV-B, although this association is not yet clearly elucidated.[88-93] In 2014, enterovirus-D68 was associated with an outbreak of severe respiratory illness and potentially acute flaccid paralysis in children and immunocompromised adults in North America[94-98]; however, the impact of this pathogen in future seasons remains unknown.

The HCoV family includes several viruses that are known to infect humans. The severe acute respiratory syndrome (SARS) outbreak originated in China in the fall of 2002 and was characterized by a life-threatening, atypical pneumonia caused by a novel coronavirus (SARS-CoV)[99] and spread by close contact with infected humans, mostly to household contacts and health care workers. The Middle East respiratory syndrome-CoV (MERS-CoV) first emerged in the Arabian Peninsula in 2012. Since then, travel-associated cases have been found in a number of countries outside the region.[100] In adults, the fatality rate is estimated to be 40%,[101] but data in pediatric patients are limited. Asymptomatic infection is common, but disease may be severe in patients with underlying medical conditions.[102] For both SARS and MERS, updates to the case definition, epidemiology, and current management guidelines can be found at www.cdc.gov. Other HCoVs have been reported to cause pneumonia in children and immunocompromised patients treated for hematologic malignancies.[103-108]

Although CMV usually causes relatively benign disease in immunocompetent hosts, it is frequently severe and often fatal in immunocompromised hosts, including patients with acquired immunodeficiency syndrome (AIDS), malignancy, congenital immune deficiencies, and transplant recipients. Among allogeneic stem cell transplant recipients, the risk of CMV pneumonia is high. With the introduction of routine antiviral prophylaxis and preemptive therapy strategies, CMV disease during the first 3 months after hematopoietic stem cell transplantation has been reduced from 20% to 30% to less than 5% in most studies, and CMV disease now primarily occurs late after transplant.[109] Risk factors for late CMV disease include primary infection or reactivation of CMV during the early period after transplant and therapy for graft-versus-host disease.[110] Among solid organ transplant recipients, the risk of CMV disease is greatest for lung transplant recipients, followed by liver, heart, and renal transplant recipients.[111,112]

Hantaviruses are known for causing hemorrhagic fevers and acute severe respiratory infection in young adults and are spread among mammals by exposure to aerosolized feces, infected urine, or other secretions. Though rare in the United States, hantaviruses can cause severe disease with high mortality by causing leakage of plasma and erythrocytes through the vascular endothelium in the lung

(hantavirus pulmonary syndrome [HPS]) or the kidneys (hemorrhagic fever with renal syndrome [HFRS]).[113,114] Supportive care, including early consideration of extracorporeal membrane oxygenation (ECMO), is crucial to successful treatment of patients with HPS.

Clinical Presentation

The clinical presentation of viral pneumonia/pneumonitis usually consists of fever, increased respiratory rate, cough, and increased work of breathing, with grunting, flaring, retracting, and use of accessory muscles in infants and young children. Decreased oral intake with increased insensible loss due to the tachypnea may lead to dehydration. Some patients have centrally mediated apnea, and other patients have an overwhelming sepsis-like syndrome, especially young infants. Rhinorrhea, conjunctivitis, otitis media, and previous exposure to an ill child or adult should raise suspicion of a viral cause. However, many patients with influenza pneumonia have no preceding upper respiratory illness. Radiographic findings generally include evidence of hyperinflation and peribronchial cuffing, and a focal or diffuse infiltrate may or may not be present. Bacterial coinfection may appear after, or concomitantly with, the viral infection.

Central Nervous System Infections

Background

Aseptic meningitis, encephalitis, and myelitis are inflammatory conditions of the central nervous system (CNS), involving the meninges, brain, and spinal cord, respectively. Disease is caused by a variety of infectious pathogens, but viruses cause most disease. Viruses gain entry to the CNS via the bloodstream (enteroviruses and arboviruses) or by direct neuronal spread (HSV and rabies). Pathogenesis may involve direct viral invasion or a vigorous virus-specific immune response resulting in damage to neurons, oligodendroglia, or the myelin components. In the latter case, disease may follow an upper respiratory tract or other infection and primarily take the form of a demyelinating process. This disease is commonly termed postinfectious encephalomyelitis or acute disseminated encephalomyelitis.

Individuals of all ages are at risk for CNS viral infections. However, neonates, older individuals, and those with immune deficiencies are prone to more frequent and serious infections.

Etiology

Potential viral causes are multiple; enteroviruses, herpesviruses, and arboviruses are responsible for most disease (see Table 108.1). Enteroviruses account for up to 99% of cases of aseptic meningitis when a cause is identified.[115] Enterovirus meningitis in older children and adults is typically self-limited and associated with few complications. In contrast, in neonates these infections may mimic bacterial sepsis and CNS involvement is often manifested as encephalitis. Parechovirus, another cause of meningoencephalitis in neonates, is a close relative of enteroviruses and clinical manifestations are similar.[116] Specific enterovirus strains, such as enterovirus

D-68 and enterovirus 71, may cause acute flaccid paralysis (associated with anterior myelitis) in children.[96,117]

HSV is a common cause of CNS infection in all ages. During the neonatal period, HSV, especially type 2, can cause encephalitis due to vertical transmission of the virus.[118] In contrast, in older children and adults, most HSV encephalitis is caused by type 1. HSV-2, however, can cause benign aseptic meningitis in association with primary and recurrent genital infections.[119] Other members of the herpesvirus family (CMV, EBV, VZV, and HHV-6) can also cause aseptic meningitis and encephalitis. CMV encephalitis occurs most often in immunosuppressed individuals.[120,121] EBV aseptic meningitis and encephalitis present with or without the classic findings of infectious mononucleosis.[122] Acute cerebellar ataxia is a common and usually benign complication of VZV infection.[123,124] VZV encephalitis may occur following or preceding varicella or zoster and can be complicated by small or large vessel vasculitis (granulomatous arteritis), which carries the potentially serious consequence of infarction.[123-126] HHV-6 encephalitis is rare in healthy children,[127] but HHV6 is the most common cause of encephalitis in patients undergoing hematopoietic stem cell transplantation, and those receiving cord blood transplantations are at especially high risk.[128]

Arboviruses (arthropod-spread viruses) are important causes of aseptic meningitis and encephalitis.[129] The specific arbovirus determines the epidemiology, morbidity, and risk of death of associated disease. The La Crosse and St. Louis encephalitis viruses account for most arboviral CNS infections in the United States. The La Crosse virus is found mainly in the Midwest; infection typically occurs in the summer and early fall and is associated with a relatively low mortality rate. The St. Louis encephalitis virus occurs in every state but is more common in the Midwest, Florida, and Texas and has been responsible for large urban outbreaks.[130,131] Eastern equine virus occurs less frequently, and mainly in the Northeast and Southeast, but carries high rates of morbidity and death.[132,133] West Nile virus encephalitis first appeared in the United States in the summer of 1999 in New York State[134] and has subsequently moved across the United States. Most individuals infected with the West Nile virus are asymptomatic or experience flulike illness; however, older individuals and those with underlying immune deficiency may develop encephalitis that could be fatal. Acute flaccid paralysis has also been associated with West Nile virus infection.[135]

Influenza has not traditionally been considered a common cause of encephalitis; however, the 2009 H1N1 influenza A pandemic challenged this thinking. Studies in both the United States[136] and Australia[137] demonstrated that 1% to 2% of individuals with 2009 H1N1 influenza had encephalitis/encephalopathy. Children, especially those with underlying neurologic disease, appeared to be at higher risk of neurologic manifestation than adults.

Lymphocytic choriomeningitis virus (LCMV) is an infrequently recognized cause of meningoencephalitis. Disease in humans arises after exposure to the urine, droppings, and saliva of infected rodents.[138] Symptoms may last for several weeks, but most patients fully recover. Measles and mumps are two vaccine-preventable causes of encephalitis. Though now rare, mumps virus accounted for a large proportion of aseptic meningitis and encephalitis cases in the United States in the prevaccine era.[139,140] Poor vaccination coverage has the potential to lead to outbreaks and increased number of cases of encephalitis. A report of a measles outbreak in

Germany exemplifies this point.[141]

Postinfectious encephalomyelitis refers to an acute self-limited demyelinating process most commonly following viral respiratory infections and varicella. In contrast, subacute sclerosing panencephalitis (SSPE) and progressive multifocal leukoencephalopathy (PML) are rare, chronic, usually fatal, demyelinating diseases due to measles and John Cunningham (JC) virus, respectively. SSPE most commonly follows 5 to 10 years after natural measles infection and may occur as often as one case per a population of 10,000 in areas of the world where the MMR vaccine is not widely used.[142] HIV may cause encephalopathy or may also be associated with certain opportunistic infections such as JC virus. Transverse myelitis has been most frequently associated with enteroviruses; however, VZV,[143,144] CMV, influenza A,[145] and HAV[145] have also been reported as causes, even in immunocompetent individuals.

Historic clues and physical findings can be helpful in focusing the search for an etiologic agent. Travel or residence in areas where arboviruses are endemic during the appropriate season for arthropod transmission should raise suspicion for arboviruses. Enteroviral diseases are also more prevalent during summer and fall months. History of a mother with recent viral illness should raise suspicion of enterovirus in a neonate. Chronic encephalitis/meningitis due to enteroviruses can occur in individuals with agammaglobulinemia. VZV encephalitis and myelitis typically follow chickenpox or zoster by weeks to months and commonly occur in older individuals or those with immunosuppression.[146] History of exposure to a bat in the appropriate clinical setting should raise the concern for rabies.

Clinical Presentation

The classic clinical presentation of viral meningitis is characterized by acute onset of fever, headache, photophobia, vomiting, and nuchal rigidity. A more chronic presentation might indicate enteroviral disease in an immunosuppressed host, whereas recurrent aseptic meningitis can be associated with HSV-2. Encephalitis is characterized by acute onset of fever and depressed consciousness, focal neurologic findings, and seizures. A chronic progressive presentation might indicate more unusual causes, such as PML and SSPE. Transverse myelitis is characterized by an abrupt onset of weakness of the limbs progressing to flaccid paralysis. Diminished deep tendon reflexes progress to nonexistent, and there is associated sensory deficit.

Cerebrospinal fluid (CSF) findings in aseptic meningitis typically include a normal glucose level, a normal to slightly elevated protein level, and a pleocytosis, of up to 1000 cells/μL. Though the pleocytosis is classically monocytic, there can be an initial predominance of polymorphonuclear cells in the first 48 hours of illness.[147] The results of brain computed tomography (CT) and magnetic resonance imaging (MRI) studies are usually normal in viral meningitis. In general, MRI is the more sensitive study for detecting acute encephalitis. Early findings include edema with minimal contrast enhancement. As disease progresses, edema and enhancement become more obvious and may be accompanied by mass effect, hemorrhagic changes, and necrosis. As the inflammation resolves, atrophy may become prominent. In HSV, CNS imaging findings often first involve the temporal lobes with subsequent spread to other areas. Changes can ultimately progress to atrophy, multicystic encephalomalacia, and gyriform high attenuation, especially in children.[49,148]

Neurodevelopmental outcomes correlated with MRI abnormalities in one study.[149] In postinfectious encephalomyelitis, lesions may be seen throughout the CNS and primarily involve the white matter, although gray matter may also be involved.

Exotic Viral Diseases

With the increase in foreign travel and the threat of bioterrorism, the potential to treat a child with an exotic viral disease exists. The relevant pathogens include Andes virus, B virus, monkeypox, and the hemorrhagic fever viruses (Ebola, Marburg, Lassa, Crimean-Congo, Argentine, and Bolivian). If one of these agents is suspected, the patient should be isolated and infection control and public health authorities should be notified immediately.[150-152]

Although a full discussion of these agents is beyond the scope of this chapter, two pathogens deserve mention, given the 2014–2015 Ebola outbreak in West Africa and the emerging threat of the chikungunya virus. Like adult patients with Ebola virus disease, children often present with a history of abrupt onset of nonspecific symptoms and signs, such as fever, malaise, headache, myalgias, and abdominal pain.[153] As the illness progresses, vomiting and diarrhea often develop and may lead to significant fluid loss and dehydration. Patients with severe disease are commonly hypotensive and have electrolyte imbalances leading to shock and multiorgan failure, sometimes accompanied by hemorrhage.[154]

Chikungunya has caused large outbreaks in Asia and Africa, and the Caribbean has been experiencing a heavy burden of disease.[155] This mosquito-borne infection typically presents with high fever, headache, photophobia, myalgias, and arthralgias, which can be severe. A maculopapular rash may also occur. In some patients, disabling arthralgias may persist for years.

Diagnosing Viral Disease

There are five primary methods to diagnose a viral infection: (1) observation of characteristic cytopathic effect in cell culture, (2) assays that link specific antibodies to the viral antigens (complement fixation, neutralization, immunofluorescence assays, enzyme-linked immunosorbent assay), (3) microscopic identification of viral inclusion bodies, (4) serologic detection of an early antibody (immunoglobulin M [IgM]) or a fourfold or higher rise in IgG antibody titers between an acute phase and (at least 10 to 14 days later) convalescent phase serum, and (5) molecular techniques that amplify target viral DNA or RNA.

If a viral cause is suspected, acute-phase serum should be held for later interpretation. It is critical that this specimen is drawn before administration of intravenous immunoglobulin (IVIG) or blood products. Samples for viral cultures and PCR testing should be collected from the appropriate sites with specific swabs, as both cotton and wood inhibit viral growth and may contain substances that inhibit the enzymes used in PCR. Nasal washes/swabs and swabs of the base of a vesicle or ulcer (for VZV, HSV) should include good cellular content, to improve the sensitivity of the assay. Table 108.2 outlines appropriate samples and testing for a number of specific viral pathogens.

TABLE 108.2

Potential Diagnostic Tests and Corresponding Specimens for Diagnosis of Viral Pathogens

Viral Agent	Specimen	Recommended Diagnostic Tests[1]
Adenovirus	NP, pharynx, BAL fluid Tissue Serum/plasma[2]	FA, culture, shell vial or rapid culture, PCR culture, PCR, histology PCR
Arboviruses (California encephalitis, Colorado tick fever, EEE, SLE, WEE, West Nile)[3]	Serum (acute and convalescent)/plasma CSF	IgM and IgG antibody,[4] PCR and immunohistochemistry for some IgM[5] and IgG antibody,[4] PCR
Chikungunya virus[3]	Serum/plasma Blood	PCR, IgM and IgG antibody[4] Culture
Coronaviruses (OC43, 229E, HKU1, NL63, SARS and MERS)[3,6]	NP aspirate (preferred for SARS/MERS) or swab, OP swab, BAL, serum/plasma (SARS/MERS), stool (SARS/MERS), tissues (SARS/MERS) Serum	PCR IgM and IgG antibody[4]
Ebola virus[3]	Blood, oral secretions	PCR
Enteroviruses (echoviruses, Coxsackie viruses, enteroviruses)[3]	CSF, pharynx Stool[7] Serum (acute and convalescent)	PCR, culture Culture IgM and IgG antibody available for some (Enterovirus D68 may not be detected by these methods)
Hantavirus[3]	Serum Tissue (lung, kidney, spleen preferred; antemortem: lung or bone marrow)	PCR, IgM and IgG antibody[4] PCR, culture and immunohistochemistry
Hepatitis Viruses		
HAV	Serum	Anti-HAV IgM, PCR
HBV	Serum/plasma Liver	HBsAg, anti-HBcAb IgM, PCR PCR
HCV	Serum/plasma Liver	Anti-HCV IgG, PCR PCR
HDV	Serum Liver	Anti-HDV IgG PCR
HEV	Serum Liver	Anti-HEV IgM PCR
Herpes Viruses		
CMV	NP or BAL Blood Serum Plasma Tissue Urine	FA, culture, shell vial or rapid culture PCR[10] Buffy coat antigen, PCR IgM and IgG antibody[4] PCR FA, culture, histology, PCR Culture, shell vial or rapid culture
EBV	Serum Plasma, CSF Tissue	IgM antibody or slide agglutination test (monospot) PCR PCR, Immunohistochemistry
HHV-6	Serum/plasma, CSF Tissue	PCR PCR, immunohistochemistry
HSV I and II	CSF, plasma Base of lesion, NP, conjunctiva, tissue Serum Stool (neonates)	PCR, culture FA, culture, PCR IgG antibody[4] Culture
VZV	Base of lesion, tissue Serum Plasma, CSF	FA and culture, PCR IgM and IgG antibody[4] PCR
Influenza A and B	NP, pharynx, BAL fluid Tissue	FA, culture, IA (rapid), PCR[9] FA, culture, PCR
JC virus[3]	Brain CSF	Brain biopsy,[8] PCR PCR
LCMV[3]	Serum CSF	IgM and IgG antibody[4] IgM
Measles (rubeola)[3]	Serum Urine, blood, NP	IgM and IgG antibody[4] Culture, PCR
SSPE	CSF	Oligoclonal bands, IgG, measles titer
Metapneumovirus	NP, BAL fluid	FA, PCR

Mumps[3]	Buccal swab Serum, CSF Pharynx, urine	PCR, culture PCR, IgM and IgG antibody[4] Culture (rarely grows)
Parechoviruses	CSF, serum/plasma, NP, pharynx, stool	PCR culture (not diagnostic because CPE same as enteroviruses)
Parainfluenza viruses	NP, BAL fluid, tissue	FA, culture, PCR
Parvovirus	Plasma Serum	PCR IgM and IgG antibody[4]
Rabies virus[3]	Serum, CSF Saliva, brain, tissues, urine Punch biopsy (nape of neck), brain	Rabies-specific antibody by neutralization assay Virus isolation/culture (rarely helpful), fluorescent microscopy (consult ID)
Retroviridae		
HIV	Serum/plasma, CSF	Screening HIVAg/Ab rapid assays DNA PCR RNA PCR
HTLV	Serum Tissue	PCR, HTLV EIA PCR
Rotavirus	Stool	EIA or latex particle agglutination assays (commercially available); electron microscopy, culture, polyacrylamide gel electrophoresis, PCR (research labs)
RSV	NP, BAL, tissue	FA, culture, shell vial culture, IA (rapid), PCR
Rubella[3]	Serum, NP, pharynx, CSF, blood, urine	IgM and IgG antibody[4] Culture

[1]Multiple diagnostic tests are available for each pathogen. Commonly recommended diagnostic tests are listed; however, if results are negative or specimens are not available, infectious disease consultation may be helpful for additional or special testing.

[2]PCR is usually run on plasma, though some laboratories may run serum samples.

[3]Pathogen may have significant public health implications and testing should be performed in consultation with infectious disease or local public health department (for enteroviruses, if enterovirus 68/71 suspected). Testing is often not available without assistance of the public health department, and recommended specimens and tests are frequently evolving; see www.cdc.gov for updates.

[4]IgM and IgG antibody may also be referred to as *serology* on laboratory request forms. For most viral pathogens, when testing for IgG it is optimal to collect acute and convalescent sera approximately 4 weeks apart.

[5]IgM antibody does not cross the blood-brain barrier. If found in CSF, IgM antibody denotes central nervous system infection.

[6]For suspected SARS or MERS, specimens should be collected from several locations at different time points following symptom onset. See http://www.cdc.gov/sars/clinical/index.html for updated diagnostic information.

[7]Enteroviruses are shed in the stool for weeks and may not be diagnostic.

[8]Gold standard.

[9]FA and rapid antigen testing have low sensitivity for 2009 novel influenza A (H1N1); PCR testing is the most sensitive and is necessary for subtyping.

[10]Because shedding of CMV occurs in the lungs of seropositive stem cell transplant recipients without overt CMV disease, the recovery of CMV DNA by PCR from BAL fluid (which is considerably more sensitive than culture) without shell vial or culture positivity is of uncertain significance. PCR for CMV DNA in BAL or biopsy fluid should thus not be ordered routinely.

Choice of test depends on clinical setting, including organ system involved and immune status of host.

BAL, bronchoalveolar lavage; *CPE,* cytopathic effect; *CSF,* cerebrospinal fluid; *EEE,* Eastern equine encephalitis; *EIA,* enzyme immunoassay; *FA,* fluorescence assay; *IA,* immunoassay; *ID,* infectious disease; *NP,* nasopharyngeal secretions; *OP,* oropharyngeal; *SLE,* St. Louis encephalitis; *WEE,* Western equine encephalitis.

Myocarditis

Electrocardiographic abnormalities are almost always present in acute myocarditis (93%–100%)[15]; findings include sinus tachycardia, low-voltage QRS complexes, and nonspecific ST and T wave changes. Both atrial and ventricular arrhythmias may be present as well as conduction abnormalities. Echocardiography reveals left ventricular dysfunction, in most cases with either segmental wall motion abnormalities or global hypokinesis. Pericardial effusions are common. Pulmonary edema, enlarged cardiac silhouette, and prominent pulmonary vasculature may be seen on a chest radiograph.

Contrast-enhanced cardiac MRI can define the location and extent of inflammation and be used to assist in diagnosis or to guide endomyocardial biopsy.[156] In a setting where myocarditis is clinically suspected, a consensus group proposed the following diagnostic criteria utilizing cardiac MRI: myocardial edema (regional or global increase in T2 signal), hyperemia or capillary leak (early gadolinium enhancement), or myocardial fibrosis (late gadolinium enhancement). If two or more of these were present, cardiac MRI correlated with histology 78% of the time.[11,157] Isolation of virus from the myocardium provides a definite viral diagnosis of myocarditis; however, this is rarely possible, even in cases of histologically proved myocarditis. Controversy now exists as to whether endomyocardial biopsy and histologic confirmation will continue to be recommended in myocarditis given the availability of cardiac MRI and the risks associated with biopsy.[158] Viral culture of peripheral specimens such as stool and nasopharyngeal secretions or the demonstration of a fourfold rise in specific viral antibody titers provides an indirect determination of causality; however, the sensitivity is low, 16% to 26% and 30% to 40%, respectively.[12,159] Molecular biological techniques such as PCR and in situ hybridization have expanded the number of viruses implicated in the etiology of myocarditis. In addition, because of the increased sensitivity of PCR, its application in myocardial tissue provides a virologic diagnosis in up to 60% of cases.[12]

Acute Liver Failure

Viral diagnosis relies on serology, detection of viral nucleic acid in serum, and detection of viral antigens or nucleic acids in tissue obtained from liver biopsy. HAV infection is confirmed by demonstrating anti-HAV IgM antibodies. In patients with acute infection, anti-HAV IgM antibodies are detectable in the serum at the onset of symptoms, peak 1 week after onset of symptoms, and become undetectable by 3 to 6 months postinfection. The presence of HBsAg in serum indicates active HBV replication and is present in acute and chronic HBV infection. Due to the destruction of actively infected hepatocytes, HBsAg may be absent in ALF and the only marker of acute HBV infection may be anti-HBcAb (anti-HBV core) IgM antibodies. HBV DNA can also be demonstrated in serum and liver tissue by PCR. Absence of HBsAg or HBV DNA in the serum does not rule out HBV as the cause of ALF, as HBV DNA has been demonstrated in liver tissue of patients in whom serologic markers did not suggest HBV infection.[160] Coinfection or superinfection with hepatitis D virus (HDV), a hepatotropic virus that causes infection only in the presence of active HBV infection, may result in more severe disease[161,162] and can be diagnosed by demonstrating anti-HDV antibodies or HDV RNA in serum.[163]

Although the newer generation antibody assays for HCV are more sensitive, anti-HCV antibodies may not be detectable early in disease. Therefore when the

epidemiology suggests possible infection with HCV, serum and liver tissue should be analyzed for HCV RNA by PCR.

HSV hepatitis is frequently a result of newly acquired infection, thus serology may not be helpful. Skin or mucosal lesions, if present, should be cultured for HSV. Liver tissue should be sent for viral culture and PCR. HSV may also be demonstrated in blood by PCR. Both serology and tissue or blood PCR can be used to diagnose infection with EBV, CMV, HHV-6, HEV, and parvovirus. Diagnosis of adenovirus and enterovirus generally requires PCR of blood and tissue or culture of infected secretions.

Pneumonia/Pneumonitis

If available, fluorescence assay (FA) or PCR testing on nasal wash specimens is the initial diagnostic test of choice for respiratory viruses, because most of these pathogens are concentrated in the nasopharynx. However, in ALRI, a lower respiratory sample by bronchoscopy may provide the best yield and may be positive even with a negative nasopharyngeal sample. The sensitivity of FAs is generally as high as 95% for RSV, influenza, and PIVs. However, many centers now have rapid PCR that will facilitate faster, more sensitive results and may include additional respiratory viruses of concern. A rapid antigen test for RSV and influenza is available; however, for pandemic 2009 H1N1 influenza A virus in particular, FA and rapid testing have shown low sensitivity.[164-167] Shell vial assays can be performed for CMV, RSV, and adenovirus. Samples can be sent for culture; this should be considered for immunocompromised and severely ill children with respiratory distress/failure of unclear etiology if PCR testing is not available. The diagnosis of hantavirus can be made by culture of the virus (which is difficult), PCR for viral RNA from serum, plasma, or tissues, or serologic testing.[114] A review of diagnostic testing options for etiologies of viral pneumonia is provided in Table 108.2.

Meningitis/Encephalitis

CSF, blood, and throat swabs should be collected for evaluation. PCR has greater sensitivity for the diagnosis of enterovirus compared with culture[168,169] and should be used whenever possible. Viral detection via throat culture can indicate current or recent infection. Rectal or stool viral cultures are less helpful because enteroviruses may be shed for weeks after infection. DNA PCR of CSF offers relatively sensitive and specific diagnosis of herpesviruses.[121] Detection of viral-specific antibodies in the CSF can add supporting evidence. The detection of HHV-6 DNA in plasma or serum confirms active systemic viral replication. Arboviruses are typically diagnosed through detection of CSF antibodies or acute and convalescent serum specimens. PCR and immunohistochemistry have also been used to diagnose arboviral infections and are available in some settings. Diagnosis of LCMV is made through serologic testing. JC virus can be detected in CSF with PCR; this appears to be a relatively sensitive and specific method for diagnosing PML.[170,171] Definitive diagnosis, however, is usually made with brain biopsy. Diagnosis of SSPE is made with the evaluation of CSF for oligoclonal bands, IgG level, and specific measles antibody titer.

Treatment for Viral Infections

In general, for most life-threatening viral infections the primary treatment is supportive. Because of improvements in intensive medical care, death from these illnesses has decreased even without the availability of specific antiviral therapy. Although lacking for many infections, there are antivirals for most of the herpes group viruses and many respiratory viruses. For most infections, the efficacy of antiviral therapy decreases if therapy is delayed, so early diagnosis and rapid initiation are essential. Consultation with an infectious disease specialist is recommended because some antiviral agents are not commercially available and new treatment modalities continue to be identified. A listing of antiviral agents, indications, and dosages is provided in Table 108.3.

TABLE 108.3

Antiviral Agents and Indications for Use

Virus	Drug of Choice/Dose[2]	Alternate Agents/Dose
Adenovirus	There is no currently approved therapy for the treatment of adenoviral infections.	Small case series in immunocompromised children have suggested potential efficacy with IV ribavirin[191]; however, there is more data for the use of cidofovir.[192-194] Antiviral therapy should be considered for immunocompromised patients with disseminated disease or severe pneumonia.
Coronavirus	There is no currently approved therapy for the treatment of coronaviral infections.	The sudden and severe nature of the SARS outbreak in 2002–2003 necessitated the use of empiric treatment strategies. A number of agents have been used, including ribavirin, lopinavir-ritonavir, oseltamivir, and corticosteroids; however, the efficacy of any of these drugs has not been established.[195,196]
Enterovirus	There is no currently approved therapy for the treatment of enteroviral infections.	
Hantavirus	There is no currently approved therapy for the treatment of hantaviral infections.	IV ribavirin has shown benefit in HFRS,[197,198] but not in HPS.[199,200] A randomized controlled trial of methylprednisolone for HPS in Chile did not demonstrate clinical benefit.[201]
Herpes Viruses		
CMV	Ganciclovir (5 mg/kg q12h × 2-3 weeks, then 5 mg/kg q24h) is primary therapy for CMV disease. IVIG (500 mg/kg qod × 2 wk then once weekly) or CMV-IG (150 mg/kg, same schedule) can be considered concurrently for CMV disease in immunocompromised patients.	Foscarnet (90 mg/kg q12h × 2-3 weeks, then 90 mg/kg q24h), cidofovir (5 mg/kg/wk; high risk of renal toxicity, use with probenecid and saline hydration). Increased efficacy of cidofovir as second-line therapy suggested in allogeneic stem cell transplant recipients with CMV pneumonia in one small study.[202]
HSV	Acyclovir (20 mg/kg/dose IV q8h) for encephalitis in neonates and children <12 years and for neonates with disseminated disease; 10 mg/kg/dose IV q8h for children >12 years.	No specific dosing recommendations are available for HSV-associated hepatitis and pneumonitis. At least 10 mg/kg/dose should be considered outside the neonatal period.
HHV-6	There is no currently approved therapy for the treatment of HHV-6 infections.	Foscarnet and ganciclovir have in vitro activity. Case reports and series show variable clinical response with one or both drugs in combination.
VZV	Acyclovir (10-12 mg/kg/dose IV q8h); high-dose acyclovir (20 mg/kg/dose) should be used for VZV encephalitis or for disease in immunocompromised children.	
Influenza A/B	Oseltamivir[1] or zanamivir (≥7 years) 10 mg (2 oral inhalations) q12h × 5 days.	Rimantadine or amantidine generally not recommended due to widespread resistance. Local circulating influenza viruses must be considered. Combination therapy as empiric treatment may be indicated during periods of concomitant circulating viruses or for severely ill immunosuppressed patients.[203,204] Single-dose IV peramivir was approved for

		influenza in adult patients in December 2014. Pediatric safety and efficacy have not been established.
JC virus	No effective therapy.	In HIV infection, treatment with combination antiretroviral therapy may improve survival. Potential role for cidofovir.[205]
Metapneumovirus	There is no currently approved therapy for the treatment of metapneumoviral infections.	Ribavirin has in vitro activity against hMPV and has been shown to decrease viral load and lung inflammation in mouse models.[206,207] Case reports suggest ribavirin and IVIG may be used successfully in immunosuppressed patients, but retrospective studies showed no benefit.[78,79,208-210]
Parechoviruses	There is no currently approved therapy for the treatment of parechoviral infections.	
Parainfluenza virus	There is no currently approved therapy for the treatment of PIV infections.	Treatment for PIV pneumonia should include coverage for copathogens.[67] Ribavirin is active in vitro and in animal models and has thus been used for treatment of PIV pneumonia in immunocompromised hosts. Anecdotal reports of the benefit of ribavirin have been highly variable, and a retrospective series of stem cell transplant recipients showed no benefit.[67,195]
RSV	Aerosolized ribavirin (6 g reconstituted in 100 mL divided tid or 6 g in 300 mL administered over 12-18 hours daily) × 5 days has been used with modest efficacy in patients with severe RSV pneumonia and in immunocompromised patients[195,211]; not recommended for uncomplicated disease.	Combination therapy with aerosolized ribavirin and palivizumab (RSV monoclonal antibody, 15 mg/kg given once) has been used for RSV pneumonia in immunocompromised and high-risk patients, but data not conclusive.[56,203,211,212]

[1]Dosing varies by age and weight. See http://www.cdc.gov/flu/professionals/antivirals/antiviral-dosage.htm for specific recommendations. In an influenza pandemic or some outbreak situations, treatment should not wait for laboratory confirmation of influenza because laboratory testing can delay treatment and because a negative rapid test for influenza does not rule out influenza.

[2]These agents are generally recommended with infectious disease consultation for the infection listed. However, please note that not all these agents are FDA approved for the indicated use.

IVIG, intravenous immunoglobulin.

Myocarditis

The mainstay of treatment for myocarditis is supportive care. Severe cases may require circulatory support in the form of extracorporeal membrane oxygenation (ECMO) or ventricular assist devices. ECMO may also serve as a bridge to cardiac transplant in cases of dilated cardiomyopathy. Aggressive therapy is warranted because both adults and children who survive their illness have a good prognosis for return to normal ventricular function.[172-174] Cardiac transplantation may be necessary for children refractory to other management. Current recommendations do not support the use of immunosuppressive therapy.[4,11,19] Treatment with high-dose IVIG has been associated with improved left ventricular function in several small studies in children[175,176]; however, this treatment showed no survival benefit in an evaluation of multi-institutional data.[2] In adults, a controlled study found IVIG to be no better than placebo for acute dilated cardiomyopathy,[176] and a Cochrane Review found no role for the routine use of IVIG in presumed viral myocarditis.[177] The use of IVIG in pediatric myocarditis warrants investigation in larger, controlled studies. Specific antiviral therapy may be indicated when the inciting viral agent has been identified; however, because most patients present weeks after the acute infection, the benefit is unclear.

Acute Liver Failure

The role of antiviral therapy in ALF is also limited. Acyclovir should be initiated if HSV is suspected or confirmed. High-dose acyclovir (60 mg/kg/day divided q8h) should be used for neonates with HSV.[178] There are reports of the successful use of tenofovir, entecavir, and lamivudine for treatment of severe acute hepatitis caused by HBV.[179-182] Liver transplantation may be required for some patients.[24,47,48] For a detailed discussion of the management of ALF, see Chapter 99.

Pneumonitis

The cornerstone of treatment remains supportive with supplemental oxygen, fluids, bronchodilators, and mechanical ventilation. Corticosteroids are generally of no proved benefit in viral-mediated pneumonia or bronchiolitis.[183,184] The use of empiric broad-spectrum antibiotics may be important until a diagnosis can be established and because some viral infections caused by PIVs, HRVs, and HCoVs may occur in the context of a bacterial coinfection. For certain immunocompromised patients, fungal copathogens should also be considered. Early isolation and infection control measures for suspected viral infections should be implemented.

A number of antiviral strategies have been investigated or employed on an anecdotal basis to treat viral pneumonia, but the only agents approved by the Food and Drug Administration include ribavirin for RSV and antivirals for influenza (oseltamivir, zanamivir, peramivir, amantadine, and rimantadine). For influenza, the strain of local circulating viruses must be considered when planning a treatment regimen. The reader is encouraged to consult http://www.cdc.gov/flu/ for national surveillance data on influenza viruses circulating in the United States. Combination therapy or the use of investigational agents may be considered during periods of concomitant circulating viruses or for severely ill immunosuppressed patients.[185-187] Table 108.3 provides a detailed summary of antiviral agents for various causes of viral pneumonia.

Encephalitis

Untreated, HSV encephalitis carries a death rate in excess of 70%.[188] Even when treated, death and complications remain on the order of 15% and 20%, respectively.[189] Similarly, despite treatment, neonatal HSV CNS disease carries significant risk of death and morbidity, ranging from 0% to 15% and 43% to 68%, respectively.[118] Early identification of patients and rapid initiation of acyclovir have been associated with better outcome.[188,189] Unless an alternative cause is clear, high-dose acyclovir should be initiated in all children with encephalitis until HSV can be ruled out. After the acute phase of treatment, oral suppressive acyclovir therapy for 6 months has been shown to improve developmental outcomes in infants with neonatal HSV and CNS involvement.[190] Other specific antiviral therapy may be directed as outlined in Table 108.3.

CHAPTER 109

Infectious Syndromes in the Pediatric Intensive Care Unit

Srinivas Murthy, Peter N. Cox

PEARLS

- Numerous clinical syndromes present similarly; knowledge of local epidemiology is crucial for timely recognition and diagnosis.
- Suspected meningococcal infections should be treated with great urgency, given the risk for rapid progression.
- Toxic shock syndromes are primarily caused by *Staphylococcus aureus* and group A streptococcus.
- Necrotizing fasciitis is a surgical emergency.
- Knowledge of local resistance patterns will allow optimal empiric therapy for suspected invasive *Streptococcus pneumoniae* infections.
- Management of Rocky Mountain spotted fever and hantavirus infections is time sensitive and requires a high degree of clinical suspicion and knowledge of local epidemiology.
- Infectious syndromes with multiorgan involvement are often caused by nonbacterial etiologies, including viruses; a broad differential diagnosis always should be considered.

The pediatric critical care unit is the epicenter of severe childhood infections in most hospitals. Many of these infectious processes are nosocomial and are associated with either patient (eg, immunocompromised) or procedural issues. Other infectious processes affect specific organs (bronchiolitis and meningitis). These specific infections and the general principles of sepsis management are described in other chapters of this book. This chapter describes selected bacterial, viral, and other infections that may precipitate a systemic response and multiorgan involvement requiring intensive care unit admission. Salient and identifying features are highlighted and, where appropriate, specific comments are provided regarding

therapeutic strategies.

Meningococcal Infection

Etiology and Epidemiology

Neisseria meningitidis is a gram-negative diplococcus that causes bacterial meningitis and invasive disease. In regions where vaccination uptake is high, rapidly declining rates have been demonstrated.[1,2] In the United States, *Neisseria meningitidis* infections have an estimated incidence of 0.123 per 100 000 people across ages, making it the fourth most common cause of bacterial meningitis overall, after *Streptococcus pneumoniae,* Staphylococcus, and gram-negative meningitis.[3] In regions without high vaccination rates, however, the incidence can be above 10 per 100,000 people.[4]

Children are disproportionately affected, however, and have higher incidence than adults, with age spikes at less than 1 year and in late adolescence.[4,5] Serogroup B remains the most common cause in North America; recently available vaccines will likely alter this epidemiology. Globally, serogroup switching is under way, with serogroup W replacing serogroup A as the most common group in the meningitis belt in Africa, given ongoing vaccination strategies against serogroup A.[6]

Case fatality rates range from 4% to 15% in United States and Canada, depending on the case series, with higher mortality in those with complement deficiencies or asplenia.[7,8] Early identification, antibiotic and fluid administration, and referral to higher levels of care are likely to have contributed to significant mortality declines.[9]

Transmission is thought to be via the aerosol route, with associated asymptomatic nasopharyngeal carriage; why some children develop invasive disease remains to be elucidated. Postexposure prophylaxis of meningococcal disease is detailed in the American Academy of Pediatrics Red Book and includes the use of rifampin or ceftriaxone for high-risk contacts, including health care providers with significant exposure to oral secretions.

Clinical Presentation

Invasive disease is typically manifested as one of three syndromes: meningitis, meningitis with meningococcemia, or meningococcemia without meningitis. Invasive meningococcal infections typically start with nonspecific symptoms over the first few hours and rapidly progress to multiorgan involvement.[10] Early signs include leg pains, abnormal skin color, and cool extremities, in addition to fever and myalgias. The classic triad of hemorrhagic rash, altered level of consciousness, and meningismus is typically a late finding. The rash is often petechial in nature and may progress to large purpuric lesions in approximately 15% to 20% of those with meningococcemia (Fig. 109.1). Risk factors for poor outcomes include a bleeding diathesis and focal neurologic signs. Traditional pediatric critical care scoring systems are adequate to predict outcome.[11,12]

FIG. 109.1 Purpura fulminans in the legs of a child with meningococcal sepsis.

Shock due to meningococcemia is often complicated by adrenal insufficiency, possibly due to adrenal infarction, otherwise termed *Waterhouse-Friderichsen syndrome*. Additionally, disseminated intravascular coagulation (DIC) is common in severe cases, with a significant coagulopathy and endothelial dysfunction leading to the classic purpura fulminans. High levels of lipopolysaccharide are associated with worse outcomes, although the exact pathophysiology remains to be determined.[13] Other syndromes associated with meningococcal infection include pericarditis, arthritis, urethritis, and pneumonia.

Diagnosis

Given its rarity, rapid progression, and nonspecific initial presentation, clinicians must maintain a high degree of suspicion for children with these symptoms. The roles of ancillary tests such as white blood cell count, C-reactive protein, and procalcitonin are unclear in risk stratification. Clinical suspicion should be based on the characteristic rash and symptoms and signs of hypoperfusion, such as tachycardia, cool peripheral extremities, decreased urine output, and altered mental state. Aggressive treatment should be instituted prior to the onset of overt shock and likely before a confirmatory diagnosis is made.

Definitive diagnosis is made with culture from blood or cerebrospinal fluid, which will be positive in approximately 50% or 80% of cases, respectively. Pretreatment with antibiotics will negatively impact the culture positivity rates, given the rapid sterilization observed.[14,15] Lumbar puncture should be delayed if evidence of increased intracranial pressure, coagulopathy, or cardiovascular instability is present. Cultures from petechial scrapings and other body fluids such as synovial fluid can be helpful; however, isolation from the nasopharynx may not be useful, given the high rates of asymptomatic carriage. Latex agglutination is helpful for CSF and urine but unreliable for blood specimens. Polymerase chain reaction (PCR) has yet to replace traditional culture techniques, given the need for formal sensitivity testing; however, its rapidity and accuracy hold great appeal.[16,17]

Management

Many of the lessons from the management of septic shock (see Chapter 111) and

meningitis (see Chapter 70) can apply in the management of patients with invasive meningococcal disease. The fundamental treatment is the early administration, within 30 minutes of consideration of meningococcal disease, of empiric antibiotic therapy.[18] Lumbar punctures should not delay antibiotic administration, and blood cultures should be drawn immediately prior to antibiotics. Reported resistance to penicillin and chloramphenicol make these agents inappropriate first-line empiric therapy. Hence, a third-generation cephalosporin such as ceftriaxone or cefotaxime is the agent of choice for empiric therapy, pending susceptibility results. Penicillin or chloramphenicol are appropriate to switch to upon obtaining appropriate susceptibility results, if a minimum inhibitory concentration of <0.1 mcg/mL is present. Dosing should ensure adequate CNS penetration. The typical duration of therapy is 7 days for meningitis or meningococcemia.

Significant capillary leakage is the hallmark feature in meningococcal sepsis. Thus the prominent problem faced in the early stages is maintenance of adequate circulating volume. Early volume resuscitation is vital and has been shown to improve outcomes in wealthy regions with access to intensive care supports.[19-22] Crystalloid is the solution of choice, with normal saline being the typical initial fluid. Significant myocardial depression should be assumed to be present with invasive meningococcal disease, especially in younger children,[23,24] and inotropes should be used early with fluid to ensure adequate cardiac output. The exact volume of fluids administered before initiating inotropes is a matter of much controversy; the authors consider the addition of inotropes after the administration of 40 to 60 mL/kg of fluids and persistent signs of hypoperfusion. To ensure appropriate and rapid volume resuscitation and inotropic delivery, central venous access should be established as soon as meningococcal sepsis is suspected; however, volume resuscitation should not be delayed and should be started with peripheral or intraosseous access if central access is not yet available.

Respiratory support often is necessary when fluid requirements are large, myocardial depression is suspected, and capillary leak is significant. Even if the patient is alert and oriented, early intubation and ventilation may be beneficial for resuscitation and transport when meningococcal infection is suspected in order to ensure adequate oxygenation, reduce the patient's work of breathing, decrease metabolic demands, secure central venous access, and maintain stability for transport.

Numerous metabolic derangements often occur because of cellular fluid shifts. Abnormal potassium, calcium, and magnesium concentrations can affect myocardial function and should be monitored and managed aggressively. Hypoglycemia is a common finding, and serum glucose concentration should be monitored closely. Metabolic acidosis is common and usually corrects with adequate perfusion and lactate clearance.

Disseminated intravascular coagulation (DIC) is common in severe meningococcal disease because of factor loss from capillary leak, endothelial activation, and clotting factor consumption. If there is significant hemorrhage, derangements are treated with fresh-frozen plasma and cryoprecipitate as needed. Plastic surgical interventions may be necessary for amputations and skin grafting after the patient has recovered from acute illness, with a large proportion of patients having significant skin or orthopedic issues.[25,26]

In addition to standard cardiovascular and respiratory support, multiple specific

treatment strategies for meningococcus have been proposed. They have been aimed at altering the inflammatory cascade, treating hemostatic abnormalities, and inducing vasodilation and perfusion. Corticosteroids for meningitis due to meningococcus have not been associated with improved mortality in meta-analyses.[27] Adrenal replacement doses of corticosteroids for refractory shock remain a consideration.[21] Numerous immunomodulatory and other novel therapies have been studied, without beneficial effect documented, and no current specific therapies are available for severe meningococcal disease.[28-31]

Toxic Shock Syndrome

Etiology and Epidemiology

Toxic shock syndrome (TSS) is a toxin-mediated systemic syndrome caused by either *Staphylococcus aureus* or *Streptococcus pyogenes* (group A streptococcus [GAS]).[32-34] It occurs across all age groups; in the UK, toxic shock syndrome has an annual incidence of 0.38/100,000 among children.[35]

Both organisms have been known to produce exotoxins that act as superantigens, where they are capable of immune system activation without proceeding through the classic antigen-recognition pathways. The massive inflammatory response and cytokine release result in multisystem disease and shock. Production of these exotoxins is subject to various physiologic and environmental parameters.[36]

S. Aureus has been shown to produce a number of exotoxins, mainly toxic shock syndrome toxin-1 (TSST-1) and Staphylococcal enterotoxin B that have been isolated from bacterial strains in affected patients. TSS first came to prominence in the 1980s in association with the use of super-absorbent tampons among young females[37]; its incidence due to menstrual cases has markedly decreased since that time. Currently about half of cases are nonmenstrual related due to other *S. Aureus* infections such as postsurgical or skin and soft tissue infections. Its overall annual incidence, as reported in a population-based surveillance study in Minnesota is 0.52 cases/100,000 population.[38]

S. pyogenes produces a number of exotoxins that are associated with TSS, most notably M-proteins produced via the *emm* gene. The incidence of streptococcal TSS appears to be relatively rising, with highest rates in young children and the elderly.[39,40] Streptococcal TSS is associated with invasive GAS infection, with the major portals of entry being skin, vagina, or pharynx. There has been an association documented with varicella infection.[41] In the same surveillance study mentioned earlier, the pediatric incidence of streptococcal TSS was equal to that for staphylococcal TSS in the UK.[35]

Clinical Presentation

Surveillance definitions for both staphylococcal and streptococcal TSS are available (Box 109.1). For staphylococcal TSS, the onset is typically abrupt, with fever, chills, malaise, and diffuse macular erythroderma. Fever often is remarkably high and resistant, occurring with intense myalgias, vomiting, and diarrhea. The rash is described as a generalized deep-red “sunburn” and can be accompanied by conjunctival erythema. Within 24 hours, cardiovascular depression becomes

prominent, with hypotension and decreasing systemic perfusion leading to severe shock and multiorgan dysfunction. As it is a toxin-mediated disease, most cases do not cause infective endocarditis. However, progressive liver and renal failures are common. The patient may manifest symptoms of diffuse toxic encephalopathy, usually without meningeal signs. Renal failure can be oliguric or nonoliguric. Scaling and desquamation, which are included in the diagnostic criteria, occur with resolution of fever and usually are prominent on the palms and soles.

Box 109.1

Surveillance Definitions for Staphylococcal and Streptococcal Toxic Shock Syndromes.[108,109]

Staphylococcal Toxic Shock Syndrome	A confirmed case includes fever, hypotension, rash, and involvement of at least three organ systems and negative results on alternative diagnoses: • Central nervous system: disorientation or alteration in consciousness, without focal neurologic signs, when fever and hypotension are absent • Gastrointestinal: vomiting or diarrhea at onset of illness • Hematologic: platelets ≤100,000 • Hepatic: total bilirubin or transaminase concentrations greater than twice the upper limit of normal • Muscular: severe myalgia or creatine phosphokinase (CPK) level greater than twice the upper limit of normal • Mucous membrane: vaginal, oropharyngeal, or conjunctival hyperemia • Renal: blood urea nitrogen or creatinine concentration greater than twice the upper limit of normal or at least five white blood cells per high-power field in the absence of urinary tract infection *And* Negative results on the following tests: • Blood, throat, or cerebrospinal fluid cultures for other organisms • Serologic tests for Rocky Mountain spotted fever, leptospirosis, or measles
Streptococcal Toxic Shock Syndrome	Isolation of group A Streptococcus from a normally sterile site (blood, CSF, pleural fluid, surgical wound) Hypotension *And* two or more of the following: • Renal dysfunction: creatinine concentration greater than twice the upper limit of normal • Hematologic: thrombocytopenia, disseminated intravascular coagulation (DIC) • Hepatic: total bilirubin or transaminase concentrations greater than twice the upper limit of normal • Respiratory: acute respiratory distress syndrome • Skin: erythematous macular rash, may desquamate, or soft tissue necrosis (ie, necrotizing fasciitis)

Streptococcal TSS is often preceded by a clear portal of infection with soft tissue findings, with a minority of cases occurring without a clear source. The symptoms and disease progression overlap with staphylococcal disease, with a diffuse erythematous rash and progressive multiorgan dysfunction with hypotension. Notably, fever is absent in the case definition of streptococcal TSS, but it is a mandatory component of diagnosis in staphylococcal TSS.

Diagnosis

Differential diagnoses for syndromes that include fever, rash, and multiorgan involvement are numerous and are summarized in Box 109.2. The diagnosis is clinical, and there is significant overlap with these syndromes. Probable TSS is diagnosed when either one characteristic is missing for staphylococcal TSS and when GAS is isolated from a nonsterile site for streptococcal TSS. Markers of inflammation

and organ and tissue perfusion speak to the severity of illness and poorly differentiate TSS from other systemic illnesses. Isolating *S. aureus* is not mandatory for fulfilling case definition criteria for staphylococcal TSS; isolating GAS is mandatory for fulfilling case definition criteria for streptococcal TSS.

Box 109.2

Differential Diagnosis of Staphylococcus TSS

Bacterial: meningococcemia, group A streptococcus, toxic shock, scarlet fever, staphylococcus scaled skin syndrome, salmonella infection, Rocky Mountain spotted fever, ehrlichiosis, leptospirosis

Viral: measles, enterovirus

Other: Stevens-Johnson syndrome, toxic epidermal necrolysis, Kawasaki disease, systemic lupus erythematosus

Management

The majority of cases of TSS will require intensive care support, given the multiorgan involvement and hypotension.[35] Hemodynamic management is similar to that for septic shock (see Chapter 111), with fluid resuscitation and vasoactive agents administered as necessary to maintain tissue perfusion, incorporating presumed myocardial depression into treatment algorithms. Respiratory support with invasive ventilation and renal support with dialysis are often required, depending on the severity of illness.

The mainstays of specific therapies for TSS are eradicating the nidus of infection and antitoxin therapies. Infection eradication is accomplished through surgical debridement, as appropriate, and aggressive antibiotic therapy. Urgent surgical consultation, for both streptococcal and staphylococcal TSS with a clear focus, is crucial for achieving source control in a timely fashion. A vaginal exam should be performed for foreign bodies in appropriate situations.

Antibiotic therapy should be appropriate for the suspected infection, and empiric therapy should include coverage for both organisms, as well as suspected resistance profiles. Standard protocols for suspected staphylococcal TSS should include an antistaphylococcal agent such as cloxacillin or nafcillin and clindamycin. In regions where methicillin-resistant *Staphylococcus aureus* (MRSA) prevalence is greater than 10%, vancomycin should be added to the empiric regimen and discontinued when susceptibility results are available. Clindamycin should be continued because of its ribosomal effects and theoretic ability to suppress ongoing toxin production.[42] Streptococcal TSS is effectively treated with high-dose penicillin. Clindamycin should be coadministered for its above-mentioned ribosomal effects, as well as its effects on slow-growing GAS species for full bacterial eradication.[43]

Toxin control is typically addressed with clindamycin and intravenous gamma-globulin (IVIG) administration.[44,45] Despite the theoretic benefit for supplementing toxin-neutralizing antibodies, only mixed data exist for IVIG efficacy in streptococcal TSS[46-49] and only anecdotal efficacy data in staphylococcal TSS.[50] The lack of efficacy in staphylococcal TSS may be due to decreased superantigen inhibition in standard

preparation IVIG, compared with streptococcal disease.[51] Regardless, it is routinely used for severe disease of both types but more so for streptococcal TSS.[35,52] The recommended dose, if administered, is 150 mg/kg to 400 mg/kg per day for 5 days or a single dose of 1 g/kg to 2 g/kg.

Prognosis

With early and aggressive therapy, prognosis is good, with a mortality rate of 4.2% in streptococcal TSS and 3% to 5% in staphylococcal TSS.[48,53] The variable mortality in streptococcal TSS, which traditionally had higher mortality compared with staphylococcal TSS, may speak to increasing diagnosis due to awareness of the disease or to improved management strategies, given mortality in the 10% to 40% range in earlier case series.[35,54,55]

Necrotizing Fasciitis

Etiology and Epidemiology

Necrotizing fasciitis is characterized by extensive local necrosis of soft tissue and skin. It is typically due to one of two microbiologic causes: type I infection, with a combination of anaerobic and aerobic bacteria, and type II infection, primarily caused by *S. Pyogenes.* Type I disease is more common in individuals with comorbid disease, including diabetes, peripheral vascular disease, and immune compromise. Type II disease can occur in healthy individuals and is the predominant type in children. Necrotizing fasciitis represents between 10% and 20% of all invasive *S. pyogenes* infections in children, with a pediatric incidence of approximately 3 cases/million population in Canada.[56,57] Overall mortality in the pediatric population is approximately 5%.[57] Several reports have implicated varicella infection and nonsteroidal antiinflammatory drugs as a risk factors for infection; however, a causal relationship has not been established.[58]

Clinical Presentation

Necrotizing fasciitis typically presents initially with severe, localized pain, often out of proportion to corresponding skin erythema. As a deep-tissue infection that results in rapid and progressive destruction of muscle, fascial, and fat layers, it can spread rapidly along these planes and produce crepitus on palpation. The legs are the most common sites of infection, but the abdominal wall, groin, and perianal areas also are frequently affected. In newborns, the site most commonly affected site is the umbilicus. Approximately 80% of infants eventually develop obvious signs of soft tissue infection, and of these 70% progress to deeper infections requiring surgical debridement. Over the first 24 to 48 hours, the area becomes erythematous and swollen without sharp margins. Skin vesicles and bullae may be bluish and may appear by days 4 to 5, heralding fasciitis. By this time, the area often becomes anesthetic and gangrenous secondary to thrombosis of small blood vessels. Marked swelling and edema may lead to compartment syndrome requiring urgent fasciotomies. There are often systemic symptoms through associated toxin production and inflammation.

Diagnosis

Signs and symptoms may not be specific for necrotizing fasciitis; thus empiric treatment is initiated before the diagnosis is confirmed and a high index of suspicion must be maintained. Bacteremia is present in 60% of type II infections and much less frequent in type I infections.[59] High serum creatinine kinase and C-reactive protein concentrations have correlated well with deeper soft tissue infections and worse outcomes.[60] Imaging can be useful to determine the extent and location of disease, but they should not delay surgery. CT is the most time-sensitive study, whereas MRI is more sensitive in the diagnosis.[61,62] Definitive diagnosis, however, can only be made with surgical exploration and direct visualization of the fascial planes and muscle tissue.

Management

When necrotizing fasciitis is suspected, aggressive hemodynamic support and prompt antibiotic therapy are essential. Surgery should be performed for aggressive debridement of necrotic tissues and accurate diagnosis to halt the progression of ongoing spread. Frequent procedures for ongoing debridement and repeat imaging to assess the extent of spread are often required during the first phase of hospitalization. Antibiotic regimens should initially consist of broad-spectrum therapy while tests are being performed, including coverage for anaerobic organisms and clindamycin for toxin production. These can be tailored if GAS is susceptible to penicillin and clindamycin. In polymicrobial necrotizing fasciitis, antibiotic coverage should remain broad and culture results may not definitively guide therapy.

Antibodies specific for the toxin do not exist, but the use of intravenous immunoglobulin (IVIG) 1 to 2 g/kg in a single dose has been effective in various case series of necrotizing fasciitis, similar to TSS as noted earlier.[46,49,63] The possible mechanism may involve prevention of T-cell proliferation and reduction of cytokine release. Some anecdotal reports of the benefits of hyperbaric oxygen also exist but are inconclusive.[64] No controlled trials have demonstrated the efficacy of either of these therapies.

Invasive Pneumococcus

Etiology and Epidemiology

Streptococcus pneumoniae is the most common cause of otitis media and a frequent cause of sinusitis. With regard to invasive disease in the critical care setting, pneumococcus most commonly presents as bacteremia, pneumonia, arthritis, and meningitis. Meningitis is discussed in Chapter 70. This chapter focuses on bacteremia and pneumonia, focusing specifically on features related to pneumococcal infection. Other less common pneumococcal infections include endocarditis, soft tissue cellulitis, pericarditis, peritonitis, and salpingitis.

S. pneumoniae is an encapsulated gram-positive diplococcus organized in chains. Transmission is via secretions and respiratory droplets and increases in environments of close contacts, such as day care centers. It is a nasopharyngeal colonizer and is found in up to 40% of healthy children, although this rate is decreasing with increasing vaccination uptake.[65,66] Invasive disease may be

secondary to mucosal barrier changes from other viral infections. In the Northern Hemisphere, invasive disease in children is more prevalent between September and May and can be associated with other viral illnesses such as influenza.[67]

The rate of invasive pneumococcal disease is rapidly declining in regions with effective vaccination strategies, with incidence rates of approximately 15 cases/100,000 population in children younger than 2, the highest incidence age group among children.[68,69] There are more than 90 serotypes of *S. pneumoniae*, with only a few identified as causing invasive disease, and current vaccination strategies address 7 or 13 of these serotypes. The incidence of invasive pneumococcal disease is higher and the severity of invasive illness greater in children with congenital or acquired humoral immunodeficiencies, including HIV, as well as deficient splenic function (Box 109.3). The majority of invasive disease across age groups is pneumonia, representing 69% of all invasive pneumococcal disease in the United States.[69] The total mortality for invasive pneumococcal disease in the United States is approximately 1% in surveillance regions, with lower mortality rates across pediatric age groups, although long-term morbidity from meningitis is common.[69-71]

Box 109.3

Risk Factors for Invasive Pneumococcal Disease

Organism: pneumococcal serotype

Host: age <2 years, ethnic background (African American, Native American, Alaskan, Micronesian), presence of concurrent viral respiratory infection, underlying illness (antibody deficiency, HIV infection, complement deficiency, splenic dysfunction, sickle cell disease, malignancy)

Environmental: day care attendance, recent antibiotic use, winter season, overcrowding, smoke exposure

Clinical Presentation

Invasive pneumococcal disease is defined as the isolation of *S. pneumoniae* from normally sterile sites such as blood, pleural fluid, joint fluid, and CSF. Presentation can be quite nonspecific, especially in infants, and relates to the organs and tissues affected. Symptoms of bacteremia can range from asymptomatic due to occult bacteremia to florid septic shock. Meningitis presents as described in Chapter 70. Pneumococcal pneumonia commonly presents with lobar infiltration, with some degree of pleural effusions in 40% of cases.[72] Bacteremia is present in approximately 10% of cases of pneumonia, increasing to 30% in cases with coincident parapneumonic effusion.[73]

Diagnosis

Diagnosis depends mostly on clinical suspicion. Isolation of bacteria from blood or normally sterile fluid confirms the diagnosis but should not delay treatment if pneumococcus is suspected. Pneumococcal PCR is available, although lacking the specificity and sensitivity for routine clinical use.[74] Sputum samples are rarely

helpful in children, and nasopharyngeal cultures or molecular testing may reflect only colonization rather than infection. If intubated, samples obtained via bronchoalveolar lavage can be beneficial. Ultrasound or computed tomography (CT) can help identify effusions or empyema, which subsequently can be aspirated and sent for appropriate testing. Often, culture results will be negative and patients will be treated for presumptive pneumococcal disease due to a consistent clinical history.

The diagnosis of pneumococcal meningitis is via microbiologic evidence of bacteria. The presence of clinical meningitis, in the setting of a positive culture from pleural fluid or blood for *S. pneumoniae,* abrogates the need for a diagnostic lumbar puncture, especially given the small, but present, risk of herniation.

Management

Treatment of invasive pneumococcal disease consists of organ-specific supportive therapy and aggressive antibiotic administration. The management of respiratory failure, meningitis, and septic shock is described in Chapters 57, 70, and 111. Antibiotic regimens are changing and are entirely contingent upon knowing local resistance patterns, with mixed evidence that infection with resistant strains is associated with worse outcomes.[75,76] Risk factors for being infected with resistant strains include recent antibiotic exposures and immunosuppressing conditions.[77] In 2012 in the United States, 95% and 100% of pneumococcal strains reported were sensitive to cefotaxime and vancomycin, respectively, with rates remaining constant.[5,69]

For critically ill patients, empiric administration of combination therapy is recommended, given the severity of disease and the possibility of resistant organisms, until susceptibility results are available. Recommended approaches include a third-generation cephalosporin such as ceftriaxone or cefotaxime (25 to 100 mg/kg/dose every 8 hours, with cefotaxime preferred if less than 1 month of age) and vancomycin at 10 mg/kg/dose every 6 hours. These recommendations do not hold for noncritically ill patients, where second-generation cephalosporins, such as cefuroxime, are recommended, without vancomycin coadministration.[73] Treatment should be continued for 7 days for uncomplicated bacteremia, 10 days for pneumonia, and 14 days for meningitis, with antibiotic choice tailored by organism susceptibilities. The roles of medical or surgical treatment of any parapneumonic effusions or empyema remain to be seen and relate to the severity of clinical disease.[73,78]

Rocky Mountain Spotted Fever

Etiology and Epidemiology

Rocky Mountain spotted fever (RMSF) is a tick-borne bacterial infection resulting in a diffuse small-vessel vasculitis with the potential for causing multisystem disease. RMSF is caused by *Rickettsia rickettsii,* a small gram-negative coccobacilli carried by dog or wood ticks endemic to the United States, Canada, Mexico, and Central and South America. In the United States, the incidence is particularly high in the southeastern, south central, and south Atlantic regions (Fig. 109.2). The disease occurs mostly in the spring and early summer months, with almost half of cases

occurring during May and June.[79] It is the most common rickettsial infection in the United States, with 7 cases/million diagnosed in 2007.[80] Case fatality rates are highest in the young and the elderly, with a total mortality rate of approximately 0.3% and a mortality of 3% to 4% in children.[80] Subclinical infection is common, with seroprevalence rates higher than incidence rates in numerous surveys.[81,82]

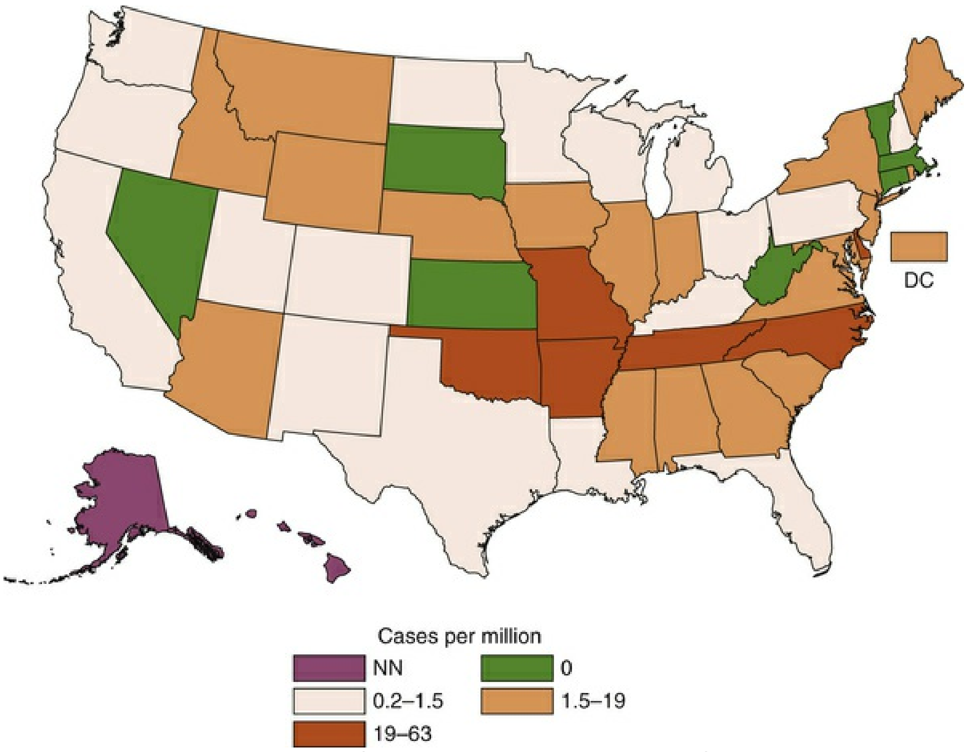

FIG. 109.2 Distribution of average reported cases of Rocky Mountain spotted fever—United States 2010. (Available at http://www.cdc.gov/rmsf/stats, accessed January 12, 2015.)

Clinical Presentation

The incubation period after a tick bite is 2 to 14 days (mean, 7 days). *R. rickettsii* gains entry into endothelial cells and leads to widespread vasculitis, increasing vascular permeability and activating inflammation and coagulation in nearly every organ. The classic symptoms of RMSF consist of fever, rash, and headache, in the appropriate geographic context, with a history of a tick bite. However, this classic triad is present in only 3% of patients in the first 3 days of illness, with typical early symptoms being a sudden onset of fever and malaise, with nausea, headache, vomiting, and abdominal pain being other frequent symptoms.[83,84] Additionally, only half of children with RMSF in one series reported a history of a tick bite.[84] The rash often begins between days 3 and 5, with blanching maculopapules classically starting at the wrists and ankles and then appearing on the palms, soles, and trunk, often becoming petechial (Fig. 109.3)[85]; up to 10% of patients, however, will not develop a rash and may have a worse outcome.[86] The presence of hemodynamic instability, renal dysfunction, encephalitis, and focal neurologic deficits on presentation is associated with worsened outcomes.[84,85]

FIG. 109.3 Palmar rash associated with Rocky Mountain spotted fever. (From Walker DH, Raoult D: Rickettsia rickettsii and other spotted fever group rickettsiae [Rocky Mountain spotted fever and other spotted fevers]. In: Mandell GL, Bennett JE, Dolin R, ed. Mandell: Principles and Practice of Infectious Diseases. 5th ed. New York: Churchill Livingstone; 2000.)

The white blood cell (WBC) count often is variable and usually is not helpful. Many patients, however, develop thrombocytopenia and anemia as the disease progresses. Liver and renal function abnormalities are common, and approximately 20% of patients will have hyponatremia and hypoalbuminemia from massive capillary leak and fluid shift. CSF shows mononuclear pleocytosis in one-third of samples, with an elevated protein concentration in 20%.[87]

The diagnosis of Rocky Mountain spotted fever is clinical, with the above-mentioned clinical findings and the appropriate geographic circumstances. In early disease, when it is imperative that treatment is initiated,[88] no reliable test is currently available. To confirm the diagnosis, serologic testing and skin biopsy are the two modalities available, typically performed in larger reference laboratories. *R. rickettsii* is unable to be cultured. Serology is typically useful only after 7 to 10 days of symptoms, with increasing sensitivity with increasing duration of illness, with sequential samples separated by weeks essential to confirm rising antibody titers.[89] Immunohistochemistry on skin biopsy specimens is nearly 100% specific and 70% sensitive for the confirmation of RMSF, should be performed where available, and is most useful within 48 to 72 hours of initiating antibiotics.[90,91] PCR testing on blood is available in certain laboratories, although it has varying utility, given the low numbers of circulating rickettsiae in acute disease.[92] The differential diagnosis of RMSF is broad and must include other tick-borne diseases, many other viral diseases, Kawasaki disease, and meningococcal infections.

Management

Empiric antibiotic therapy is essential early in the course of illness because fatal outcomes have been linked to missed or delayed diagnosis and treatment.[93] The drug of choice for treatment of RMSF in all age groups is doxycycline, with no ongoing controversy about its use in small children in these circumstances.[89] It is effective both orally and intravenously and should be continued for at least 3 days after symptoms subside, typically for a total of 5 to 7 days. The typical dose for children is 2.2 mg/kg/dose, administered twice daily. Chloramphenicol is a second-line agent, due to its side effect profile and reports of higher case fatality rates with its usage.[94] Given the differential diagnosis and the lack of confirmatory diagnosis, broad-spectrum agents such as ceftriaxone should be additionally considered to

cover other bacterial infections, most notably meningococcal infection.

Along with antibiotic therapy, aggressive supportive measures must be instituted. Restoration of massive fluid imbalances and cardiovascular support may be necessary. Correction of electrolyte abnormalities and coagulopathy are essential, and close monitoring of liver and renal dysfunction is indicated.

Prognosis

The case fatality rate for identified cases of RMSF in children is approximately 2% to 3%.[84,95] The major prognostic factor for mortality is delayed treatment, emphasizing the role of maintaining a high index of suspicion in affected regions.[89] Other poor prognostic factors include older patients and those treated solely with chloramphenicol.[95]

Hantavirus

Etiology and Epidemiology

Invasive infections manifesting as sepsis syndromes can be caused by nonbacterial microbes including enterovirus and influenza virus species. These are discussed in Chapter 108. This chapter focuses on more rare viruses with specific cardiopulmonary syndromes; a classic example is hantavirus, which can cause a hemorrhagic fever with renal syndrome (HFRS) in eastern Asia and Europe or a cardiopulmonary syndrome in the Americas. It is an infrequent illness, with a total of 637 cases ever reported in the United States as of December 31, 2013, with a mean age of 37 (range 6-83 years). It has been diagnosed in 34 states, predominantly in the southwestern United States (Fig. 109.4).[96]

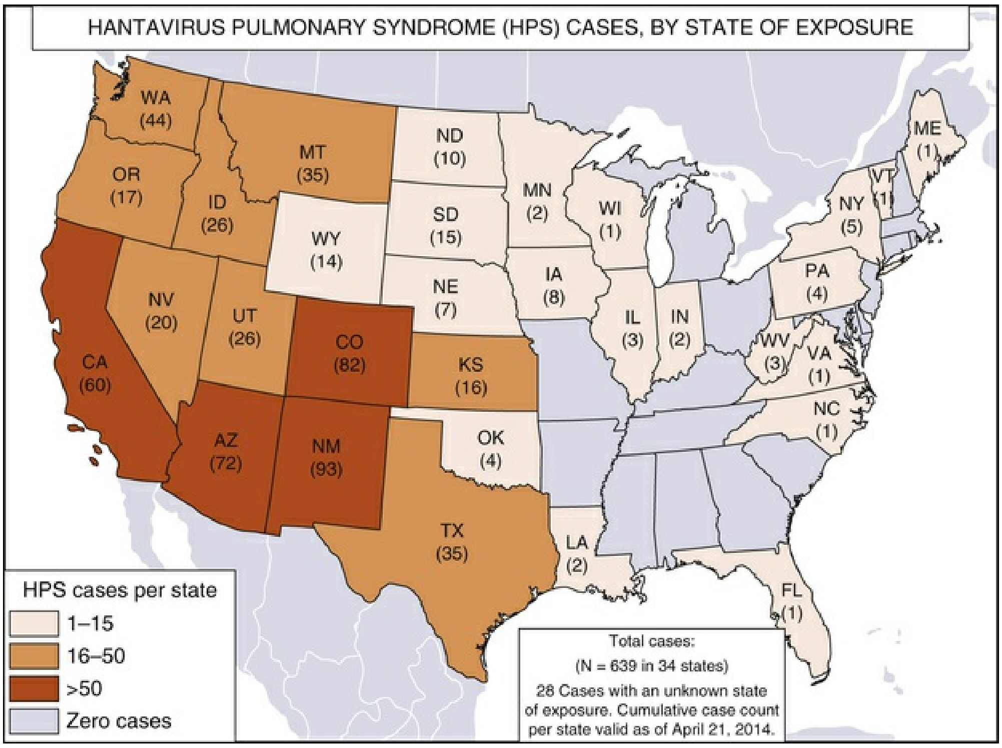

FIG. 109.4 Distribution of reported cases of hantavirus pulmonary syndrome—United States 2014. (Available at http://www.cdc.gov/hantavirus/surveillance/state-of-exposure.html, accessed January 12, 2015.)

Hantavirus has been linked to mice and rat species endemic to many areas in both urban and rural environments. The deer mouse is the main vector in rural areas throughout the United States and Canada. Infection occurs most commonly via inhalation of aerosolized saliva or excreta of infected rodents. The virus subsequently invades the pulmonary mucosa after inhalation with typically a 2-week incubation period, causing direct cellular damage that leads to increased vascular permeability.

Clinical Presentation

Both invasive hantavirus syndromes present with initial nonspecific symptoms, with rapid progression. Presentation in HFRS patients typically progresses to severe fevers and shock, with patients subsequently developing renal insufficiency and bleeding. Disease progression classically occurs along five phases, namely febrile, hypotensive, oliguric, diuretic, and convalescent phases, although this exact progression is not always present.[97]

Hantavirus cardiopulmonary syndrome often starts with fever, myalgias, and gastrointestinal symptoms and can rapidly progress over the course of days, heralded by worsening cough, to include severe pulmonary capillary leak, progressive hypoxia, and shock.[98,99]

Diagnosis

The diagnosis centers on maintaining a high degree of suspicion in affected areas. PCR and serology are available in reference laboratories and should be performed at the earliest possible opportunity, given the rapid progression of disease. Other laboratory parameters notable for hantavirus infection include a thrombocytopenia, elevated partial thromboplastin time (PTT), and an elevated hematocrit.[100]

Management

Upon diagnosis, affected patients should be triaged to higher levels of care at the earliest possible opportunity, given the rapidity of disease progression. It is often self-limited, with a case fatality rate of about 1%. Recovery typically occurs over a course of weeks.[101] However, patients often require substantial supportive care during this cardiopulmonary phase. Ribavirin is *effective in vitro* and has proved efficacious for HFRS, although data are lacking for the cardiopulmonary syndrome.[102] Current literature does not support a role for corticosteroids.[103] Given the self-limited course of illness, extracorporeal membrane oxygenation for refractory respiratory failure or hemodynamic support has been effectively used in centers where it is routinely available.[104,105]

Prognosis

Overall mortality rate is 30% to 40% with hantavirus infection and usually is

secondary to severe hypotension and respiratory failure.[106,107] Case fatality rates in children younger than 10 have been approximately 20% in the United States since the 1990s.[107]

CHAPTER 110

Hospital-Acquired Infection in the Pediatric Intensive Care Unit

Epidemiology and Control

Srinivas Murthy, Peter Skippen

PEARLS

- Handwashing is the most important means of preventing nosocomial infection. Each pediatric ICU (PICU) should develop programs to increase compliance with hand hygiene.
- All nonessential invasive devices should be removed. PICU practitioners should establish routines that require individual patient evaluation of device use daily.
- A comprehensive infection prevention and control program allied with organizational quality and patient safety programs is an essential strategy for minimizing hospital-acquired infections. Critical care teams should establish strong collaborative partnerships with the infection prevention and control service.
- Antimicrobial stewardship aims to minimize overexposure and unnecessary use of broad-spectrum antibiotics. Antibiotic-resistant bacteria are an increasing concern as a cause of hospital-acquired infection, requiring a multipronged approach to control that includes adherence to isolation procedures, appropriate use of antibiotics, educational interventions, prescribing guidelines, and restriction of the use of some antibiotics. Parents and visitors should be made partners of the infection control team to help prevent infection in their children.

Burden of Illness and Scope of the Problem

Children ill enough to require admission to a critical care unit are among the most

vulnerable to infection in the hospital for a variety of reasons. Normal physical defenses such as skin integrity, the cough reflex, and gastric motility are interrupted in the critically ill child. Innate and adaptive immunity are compromised during high-acuity acute illness. Broad-spectrum antibiotics used as empiric therapy for suspected sepsis may disrupt normal protective flora and permit overgrowth by pathogenic bacteria and fungi. Younger children with maturing immune systems are more likely to require ICU admission than older children. Additionally, children with incomplete vaccine series, either because of parental choice or other reasons, are more susceptible to communicable diseases such as pertussis and measles.

For all of these reasons, health care–associated infections remain common, occurring in approximately 9% to 21% of critically ill children in the United States.[1,2] The most common health care–associated infections (HAIs) in the PICU are primary bloodstream infections (BSIs) ventilator-associated pneumonia, and catheter-associated urinary tract infections. HAIs increase length of stay and morbidity and mortality rates for both adult and pediatric critically ill patients. This translates to an economic burden on the system as a whole.[3]

There has been renewed emphasis in the past decade on systematic strategies for preventing HAIs, both from a patient safety perspective and in an effort to reduce the cost of health care. Infection prevention and control, patient safety, patient advocates, and health care providers alike see the value of improved health outcomes associated with reduction in nosocomial infections.

This chapter reviews the epidemiologic principles underlying infection prevention and control measures and recommends interventions to prevent the most common HAIs in the PICU.

Epidemiologic Principles of Infection Prevention and Control

Chain of Infection

The transmissibility of microorganisms between infected or colonized persons and susceptible hosts was perhaps most convincingly demonstrated in the 1847 observations of Ignaz Semmelweiss, who introduced handwashing to the obstetric wards of an Austrian maternity hospital and subsequently observed a reduction in the rates of puerperal fever.[4] In this instance, the initiation of hand hygiene after patient contact (cadavers) interrupted the spread of the infectious agent (group A *Streptococcus*) via the route of transmission (hands). Over time the epidemiologic roles of the susceptible host, infected person, and route of infection were more clearly elucidated and came to be known as the *chain of infection.* The interaction among these three components is dynamic, and infection may be favored when the host is more susceptible, the infectious agent is more virulent, or the route of transmission is more facilitating.

Once admitted to the ICU, children become more vulnerable to infection because of the interventions needed to provide life-sustaining care, as well as the close contact of multiple care providers. An infectious agent that is a harmless or helpful commensal in a normal host can become a life-threatening pathogen in the ICU patient. Because of frequent antibiotic use, the spectrum of infecting microorganisms

in the hospital, particularly the ICU, is usually more pathogenic that microorganisms acquired in the community setting. Finally, the route of transmission of infection in the ICU is facilitated through frequent patient contact by health care workers, use of mechanical devices and medical therapies that disrupt natural defenses, and inadequate attention to infection prevention and control measures that prevent spread of infection to and between patients (Box 110.1). Open design wards and critical care units rather than single-room design, shared toys, pet visiting, and communal play areas also provide many opportunities for transmission of infection.

Box 110.1

Factors That Influence Risk of Infection in Pediatric Intensive Care Unit

Factors That Influence Exposure

Host Factors

Loss of skin integrity (eg, intravascular devices)

Loss of respiratory defenses such as cough, cilia propulsion (eg, intubation, sedation)

Loss of gastrointestinal defenses such as low pH, motility (eg, use of H2 blockers, nasogastric tubes)

Anatomic defect (eg, surgical site)

Environmental Factors

Crowding in the ICU

High patient/health care worker ratios (decreased time for infection prevention measures)

Use of prophylactic antibiotics (alters colonizing normal flora, allows overgrowth of pathogens)

Infection prevention and control practices of ICU health care workers

Immunization status of health care workers

Visitor policies

Reservoirs of infectious organisms in the ICU (eg, health care workers who are carriers, environmental reservoirs)

Factors That Influence Likelihood of Infection If Exposed

Host Factors

Age

Gender

Genetic makeup

Coexisting infection

Nutritional status

Use of immunosuppressive agents, including systemic steroids

Immunization status

Immune deficiency

Infectious Agent

Virulence

Antimicrobial resistance

Routes of Infectious Disease Transmission

Infectious diseases, whether bacterial, viral, protozoal, fungal, or helminthic, are transmitted via one or more of three routes, usually categorized for infection control purposes as contact (direct or indirect), droplet, or airborne (Table 110.1).

TABLE 110.1

Modes of Transmission of Microorganisms in the ICU

Mode of Transmission	How Organisms Are Transmitted	Example
Direct	Direct physical contact between an infected or colonized individual and a susceptible host.	Visitor asymptomatically shedding herpes simplex virus kisses postoperative transplant patient.
Indirect	Passive transfer of microorganisms to a susceptible host via an intermediate object such as contaminated hands that are not washed between patients or contaminated instruments or other inanimate objects in the patient's immediate environment.	Health care worker provides care to patient with *Clostridium difficile* diarrhea, does not perform adequate hand hygiene, then enters room of a noncolonized patient and handles bedding and bedrails, leaving *C. difficile* spores in susceptible patient's environment.
Droplet	Large droplets (≥5 μm in diameter) generated from the respiratory tract of the source (infected individual) during coughing or sneezing or during procedures such as suctioning or bronchoscopy. These droplets are propelled a distance of <1 m through the air and are deposited on the nasal or oral mucosa of the new host (newly infected individual) or in the immediate environment. These large droplets do not remain suspended in the air; therefore special ventilation is not required since true aerosolization (see below) does not occur.	Health care worker with influenza virus infection sheds respiratory secretions on the face of a pediatric ICU patient.
Airborne	Dissemination of microorganisms by aerosolization. Organisms are contained in droplet nuclei, airborne particles <5 μm in size that result from evaporation of large droplets, or in dust particles containing skin squames and other debris that remain suspended in the air for long periods. Such microorganisms are widely dispersed by air currents and inhaled by susceptible hosts who may be some distance away from the source patients or individuals, even in	Patient with measles is housed on an open ward in the emergency department; airborne virus particles are carried throughout the department and inhaled by susceptible hosts.

	different rooms or hospital wards.	

Contact transmission includes direct contact and indirect contact and includes transmission of *Clostridium difficile* and methicillin-resistant *Staphylococcus aureus*. *Direct contact* transmission occurs when organisms are transferred through physical contact from an infected or colonized person to a susceptible host. *Indirect contact* transmission occurs when microorganisms are passively transferred to a susceptible host via an intermediate object, such as a contaminated medical device, inanimate objects in the patient's physical environment, or contaminated hands.

Droplet transmission is the transfer of microorganisms through large droplets (≥5 μm in diameter) generated from the respiratory tract of an infected or colonized person (the source) that are propelled 1 to 2 m from the source and land on the nasal or oral mucosa of the susceptible host or in the immediate environment. The droplets can be propelled from the respiratory tract in the course of coughing, sneezing, vomiting, or singing or during procedures such as suctioning. These large droplets are propelled a distance of less than 2 m through the air but do not remain suspended in the air; that is, they do not become aerosolized. Examples of organisms transmitted via the droplet route include influenza and pertussis.

Airborne transmission refers to the spread of microorganisms in particles that are very small (<5 μm) and can therefore remain suspended in the air and widely dispersed to places far from the host. Airborne particles are created through the evaporation of large droplets or may exist in dust particles containing skin squamous cells and other debris. Measles and tuberculosis are the best-known examples of airborne transmission.

Infection Prevention and Control Measures

Infection Prevention and Control Team

Prevention of infection in patients receiving health care is the responsibility of all health care providers. Although infection prevention and control professionals (ICPs) provide an essential expertise,[5] it is important that the PICU team establish ongoing multidisciplinary processes to reduce infection risk. Among the activities the multidisciplinary team will address are the integration of surveillance data into formal plans for improvement of patient care at regular intervals and designing and implementing quality improvement initiatives. The collaborators in these initiatives can be infection control practitioners, the hospital epidemiologist or medical director of infection control, a clinical pharmacist, members of quality and patient safety departments, and representatives from nursing, ICU physicians, and respiratory therapy. Others may be necessary depending on the issue at hand, such as housekeeping or information technology.

Isolation Practices: Standard Precautions

Schema to classify infection prevention and control techniques have evolved over time from systems in which a microbiologic laboratory isolate was required (eg, disease-specific *Salmonella* diarrhea isolation), to systems focused on preventing transmission of blood-borne diseases to health care workers (Universal Precautions), to the present system in which certain practices are followed continuously with all

patients and supplemented on the basis of syndromic presentation and/or specific laboratory diagnoses. In Canada and the United States, procedures and practices that should be continuously practiced in health care settings are termed *Standard Precautions* and *Routine Practices,* respectively, and are briefly outlined in Table 110.1. The concept of Standard Precautions, in which the health care worker has a responsibility to practice certain behaviors (eg, hand hygiene) or use certain interventions (eg, wear a mask when face-to-face with a coughing patient) based on a recognition of the *need* to do so rather than because they were asked to do so, has not yet been universally adopted in health care settings. Training in these skills should be considered an essential component of health care worker competency.

The basic components of Standard Precautions are hand hygiene, use of personal protective equipment (PPE) (eg, gowns, gloves, masks, face shields) based on the nature of the health care worker-patient interaction, and the extent of anticipated body fluid exposure, respiratory/cough etiquette, and safe injection practices.

Respiratory Etiquette/Cough Hygiene Practices are measures to contain respiratory secretions and include covering one's cough (eg, coughing into a tissue or the elbow), promptly disposing of tissues, and performing hand hygiene after touching respiratory secretions.

Safe Injection Practices are basic principles of aseptic technique in the preparation and delivery of parenteral medication that limit the risk of infectious disease transmission for both the health care provider and the patient. They include preferential use of single-dose over multidose vials and use of sterile, single-use, disposable needles (needleless access devices) and syringes.

Isolation Practices: Additional Precautions

The specific type of isolation practice (routine, additional) is based on the scientific understanding of how infectious diseases are transmitted from a host or inanimate reservoir to a susceptible host and aims to control or eliminate the reservoir or infectious agent, interrupt transmission, and protect susceptible persons.

If a patient has symptoms or a diagnosis of a communicable infectious disease (eg, cough, diarrhea, rash), then Additional Precautions may be required in addition to Standard Precautions. The three standard types of Additional Precautions are contact, droplet, and airborne, as described earlier. Readers are referred to comprehensive guidelines available from public health agencies such as the US Centers for Disease Control and Prevention (CDC) or from the relevant agency in the jurisdiction in which they practice.

Contact Precautions are intended to prevent transmission of infectious agents that are spread by direct or indirect contact with the patient or the patient's environment. In addition to Standard Precautions, for example, gloves are required for all entries to a patient's room rather than just when patient interaction will occur.

Droplet Precautions are intended to prevent transmission of pathogens through close respiratory or mucous membrane contact with respiratory secretions. In addition to Standard Precautions, for example, health care workers and others coming within 3 to 6 feet of a patient on Droplet Precautions would be required to wear facial protection (mask, goggles, and/or face shield), a gown, and gloves. A child on Droplet Precautions would generally be placed in a room alone to avoid contact with other children. (Note: Some guidelines refer to a 3-ft perimeter of an

infectious person on Droplet Precautions, and others refer to a 6-ft distance. The worldwide experience with the severe acute respiratory syndrome (SARS) virus, in which droplet transmission may have occurred up to 6 ft from the source, has led some jurisdictions to implement a 6-ft perimeter for droplet precautions.)

A patient on Airborne Precautions must be placed in a room alone with special air handling and ventilation capacity. PPE that should be donned by health care workers entering the room of a patient on Airborne Precautions includes a gown, gloves, and a surgical (procedure) mask or respirator depending on the disease encountered.

Enhanced precautions for emerging and highly infectious diseases such as avian influenza and viral hemorrhagic fevers must incorporate the care setting and nature of transmission of the virus. Recent experiences with Ebola virus disease, for example, demonstrate the need for constant reassessment of the capacity for adequate infection control in facilities for emerging and novel infections and for basing infection-control practices on available science.[6]

Determining which physical setting is safest for the child while minimizing risk of transmission of infectious disease from a potentially or definitely infected patient can often be challenging. Within Additional Precautions recommendations is guidance about the need for a single room (eg, whether shared rooms are acceptable) or whether a room with special air handling is required.

There are inherent and substantial safety risks associated with isolation practices.[7] Isolation practices such as single rooms and PPE may limit the number and type of encounters health care workers have with patients because of the cumbersome nature of entering a room, breaking coverage, the discomfort of certain PPE, and the need to come and go to bring equipment, documentation, and other materials.[8] Experience with the care of patients with Ebola virus disease provides a good example of limitations on care due to the isolation practices in place. Limited encounters may inhibit the critical care team's ability to access and assess accurately the child and family, with adult studies suggesting increased HAI risk with lower nurse/patient ratios.[9] Although no conclusions can be drawn regarding recommended staffing levels for isolated patients in the PICU, this evidence suggests that increased vigilance is warranted for these critically ill children.

Hand Hygiene

Contaminated hands of health care workers have been shown in many studies to transmit health care–associated pathogens. The World Health Organization patient safety initiative on hand hygiene emphasizes five moments for hand hygiene: before touching a patient, before clean/aseptic procedures, after body fluid exposure/risk, after touching a patient, and after touching patient surroundings.

The advent of waterless hand hygiene agents has been a particularly important development for the critical care setting because of superior antimicrobial killing, time saved compared with water-based handwashing, rapid action, no risk of antimicrobial resistance, and the ease with which waterless agents can be stationed close to the point of patient care. Alcohol-based hand rubs are in general the preferred hand hygiene product for all health care settings.[10] When hands have visible dirt or organic matter (eg, blood), they must be cleaned with water and soap.

Although the benefits of proper hand hygiene far outweigh the risks, skin

irritation and health care worker attitudes about hand hygiene products can be an impediment to compliance and satisfaction with hand hygiene agents and must be considered when choosing a particular product in a specific health care setting. The role of ancillary hand-hygiene measures such as banning watches, long sleeves, and hand jewelry has been used in various jurisdictions to good effect, though controlled data for their efficacy are lacking.[11,12]

Personal Protective Equipment

PPE consists of clothing or devices donned by health care workers for their safety or protection while performing potentially hazardous patient care activity. To interrupt infectious disease transmission, eye protection (goggles or face shield), masks, gowns, and gloves may be worn as a part of Standard Precautions and Transmission-Based Precautions.

A surgical (procedure) mask provides adequate facial protection against droplets generated from the respiratory tract. Surgical masks are also used for source control (eg, on a coughing patient) as a part of respiratory hygiene/cough etiquette. To protect against airborne particles, a particulate filtering face piece respirator is required because it is thought to filter at least 95% of the smaller airborne particles. Airborne particles are known to be produced in certain infectious diseases (eg, tuberculosis, varicella, measles) or may be produced during aerosol-generating procedures in the ICU (eg, intubation) in patients with respiratory infections (eg, influenza, SARS). In a randomized controlled trial during influenza season, surgical masks were not inferior to respirators in preventing influenza transmission.[13] Readers are referred to local public health and infection control authorities for jurisdiction-specific guidance.

Surveillance

Surveillance for HAIs in a PICU is a process in which information about infections acquired after admission is summarized and given back to the care team in a timely manner so that problems can be identified for action. Surveillance has been defined as a "comprehensive method of measuring outcomes and related processes of care, analyzing the data, and providing information to members of the health care team to assist in improving those outcomes and processes."[14]

In the PICU, the most important complications are bloodstream infections and ventilator-associated pneumonia.[15,16] Other important surveillance targets in the PICU are urinary tract infection associated with catheterization, surgical site infections, and acquisition of epidemiologically important pathogens such as methicillin-resistant *S. aureus* (MRSA),vancomycin-resistant enterococcus (VRE), or other antibiotic-resistant organisms.

The National Health Safety Network (NHSN) of the CDC is a national surveillance system that collects data from a sample of health care facilities that voluntarily submit data on the occurrence of certain HAIs. Because standardized methodology and definitions and risk-adjusted data are used in the NHSN, the surveillance data permit recognition of trends, identification of practices associated with prevention of HAIs, and comparison of rates within and between facilities. Relevant to the PICU setting, NHSN reports central line–associated BSI (CLA-BSI) rates (number of

infections per central line days), central line utilization ratio (central line days per patient days), urinary catheter–associated infection (UTI) rate and utilization ratios, and ventilator-associated pneumonia (VAP) rate (VAP days per ventilator days) and utilization. It is important to note that these rates are device specific and therefore incorporate the effect of exposure to an important risk factor. Surveillance results from the NHSN are updated periodically and published in medical journals and on the CDC website.

Standard surveillance definitions have been developed by the CDC (Table 110.2). The CDC definitions incorporate subcategories for children younger than 1 year in recognition of the variable clinical presentation of infection by age. However, CDC definitions may be difficult to apply in children and are often criticized as being overly subjective and easy to manipulate, and alternative approaches have been explored.[17-21]

TABLE 110.2

Summary of Centers for Disease Control and Prevention (CDC)/National Healthcare Safety Network (NHSN) Definitions for Health Care–Associated Infections (HAIs)

This summary of the CDC/NHSN surveillance definitions for HAIs and criteria is not comprehensive. The reader is directed to up-to-date information available on the website of the National Healthcare Safety Network.[80]		
Bloodstream infection	Laboratory confirmed *(infections must be primary)*	*Regardless of age:* Recognized pathogen from ≥1 blood culture, *or* Common skin contaminant in ≥2 blood cultures associated with symptoms (fever, chills, hypotension)
		≤1 yr of age: Common skin contaminant in ≥2 blood cultures, *and* Associated with symptoms (fever >38°C or <37°C, apnea, bradycardia)
	Clinical sepsis	Applies only to ≤1 yr of age: Symptoms (fever >38°C or <37°C, apnea, bradycardia), *and* Negative or no blood culture done, *and* Physician initiates sepsis treatment, *and* No primary infection elsewhere
Systemic infection	Disseminated infection	Infections, usually of viral origin, without an apparent single site of infection and involving multiple organs and systems (eg, varicella)
UTI	Symptomatic	≥10^5 Microorganisms/mL urine, not >2 species, and symptoms (at least one of the following: fever >38°C, urgency, frequency, dysuria, suprapubic tenderness)
		Symptoms (at least 2 of the following: fever >38°C, urgency, frequency, dysuria, suprapubic tenderness) *and* at least 1 of 5 urinary laboratory criteria *or* physician diagnosis *or* treatment for UTI Separate criteria are available for children ≤1 yr without nonspecific symptoms (not referent to the urinary tract) *and* 1 of 7 laboratory criteria
	Asymptomatic	Indwelling urinary catheter within 7 days before urine culture, *and* ≥10^5 Microorganisms/mL urine, not >2 species, *and* Asymptomatic, *or* No indwelling urinary catheter within 7 days of urine culture, *and* ≥10^5 Microorganisms/mL urine, not >2 species in 2 urine cultures with same organism(s)
Pneumonia (alternate criteria are used for the diagnosis of pneumonia in adults)	Clinically defined (infants and children)	Serial chest radiographs (≥1 for patients without underlying disease and ≥2 for patient with underlying disease) with new or progressive and persistent infiltrate or consolidation or cavitation, or pneumatoceles (in ≤1 yr old), and Clinical signs and symptoms (vary according to the patient age: ≤1 yr or ≥1 yr and ≤12 yr)
Lower respiratory tract, not pneumonia	Bronchitis, tracheobronchitis, other lung infection	No clinical or radiographic evidence of pneumonia, *and* ≥2 symptoms or signs (fever >38°C, cough, new or increased sputum production, rhonchi, wheezing), *and* ≥1 positive cultures from deep tracheal aspirate or bronchoscopy *or* positive antigen test on respiratory secretions, *or*

		Child ≤1 yr with no clinical or radiographic evidence of pneumonia, *and* ≥2 symptoms or signs (fever >38°C, cough, new or increased sputum production, rhonchi, wheezing, respiratory distress, apnea, or bradycardia), *and* One or more of the following: positive culture from deep tracheal aspirate or bronchoscopy *or* positive antigen test on respiratory secretions, *or* serologic diagnosis
Ear, eye, nose, throat, mouth	Conjunctivitis	Pathogen cultured from purulent exudate from conjunctiva or contiguous tissues, *or* Patient has redness or swelling of conjunctiva or periorbital area and white blood cells and organisms on Gram stain *or* purulent exudate, positive antigen test on exudate, *or* conjunctival scraping, positive viral culture, serologic diagnosis, or multinucleated giant cells on microscopic examination of conjunctival exudate
	Sinusitis (separate criteria exist for oral cavity, ear and mastoid infections, eye infections other than conjunctivitis, and pharyngitis, laryngitis, and epiglottitis)	≥1 of the following: Organism cultured from purulent material from sinus cavity, *or* ≥1 of the following signs or symptoms with no other recognized cause: fever >38°C, pain or tenderness over the involved sinus, headache, purulent exudate, or nasal obstruction, *and/or* positive transillumination or positive radiographic examination
CNS	Intracranial infection	≥1 of the following: Organisms cultured from brain tissue, *or* Abscess or intracranial infection seen during surgical operation, *or* Selected CNS symptoms without another cause *and* 1 of 4 laboratory criteria, *or* Patient ≤1 yr with at least 1of 5 selected symptoms *and* 1 of 5 laboratory criteria
	Meningitis or ventriculitis	Organisms cultured from cerebrospinal fluid, *or* ≥1 of the following symptoms: fever, headache, stiff neck, meningeal signs, cranial nerve signs, irritability, *and* 1 of 5 laboratory criteria, *or* Patient ≤1 yr with at least of 1 of 5 selected symptoms *and* 1 of 5 laboratory criteria
	Spinal abscess without meningitis	Organisms cultured from abscess in the spinal epidural or subdural space, *or* Abscess in spinal epidural or subdural space seen during surgery, autopsy, or in histopathologic examination
SSI	Superficial incisional, primary or secondary	Occurs within 30 days of operative procedure, *and* Involves only skin and subcutaneous tissue of the incision, *and* ≥1 of the following: purulent drainage from incision, organisms isolated from aseptically obtained incisional fluid or tissue, one sign or symptom (pain, tenderness, redness, swelling, heat), *and* Surgeon opens incision and incision is not cultured or is culture positive
	Deep incisional, primary or secondary	Occurs within 30 days of operative procedure or within 1 yr if an implant is left in place, *and* Involves deep soft tissues of the incision, *and* ≥1 of the following: purulent drainage from the deep incision but not from the organ/space of the surgical site, spontaneous dehiscence of surgical site or symptomatic patient has site opened by surgeon and incision is not cultured or is culture positive, abscess found on direct examination (radiologic, histopathologic, or during operation), or surgeon diagnosis
	Organ space, primary or secondary, indicated specific type (eg, cardiac)	Occurs within 30 days of operative procedure or within 1 yr if an implant is left in place, *and* Infection involves any part of the body, excluding superficial or deep incisional areas, opened or manipulated during the operative procedure, *and* Patient has 1 of the following: purulent drainage via a drain placed into organ/space; organisms cultured from aseptically obtained specimen from organ/space; abscess found on direct examination, during reoperation, or by radiologic or histologic examination or surgeon diagnosis
Bone and joint infection (separate criteria exist for joint or bursa infection and disc space infection)	Bone (osteomyelitis)	≥1 of the following: Organisms cultured from bone, diagnosis based on direct examination during surgery or on histopathologic examination, *or* ≥2 symptoms (fever >38°C, localized swelling, tenderness, heat, or drainage at bone site), *and* 1 laboratory finding (positive blood culture or blood antigen test

		or radiographic evidence of infection)
Cardiovascular system	Mediastinitis (separate criteria exist for endocarditis, myocarditis, pericarditis, and vascular infection)	≥1 of the following*: Organisms isolated from mediastinal tissue or fluid obtained by aspirate or during surgery, *or* Diagnosis during surgical procedure or by histopathologic examination, *or* Presence of one or more of the following signs or symptoms: fever >38°C, chest pain, or sternal instability, *and* ≥1 of the following: mediastinal widening on chest radiograph, purulent drainage, or organism cultured from drainage
Gastrointestinal (separate criteria exist for hepatitis, gastrointestinal tract infections, and intra-abdominal infection)	Gastroenteritis	≥1 of the following: Acute-onset liquid stools for >12 hr with or without vomiting or fever and no likely noninfectious cause, *or* ≥2 of following signs and symptoms: nausea, vomiting, abdominal pain, fever >38°C, or headache, *and* ≥1 of the following: enteric pathogen detected in stool or rectal swab (by culture, routine or electron microscopy, or cytopathic change in tissue culture), or enteric pathogen detected by antigen or antibody assay on blood or feces
	Necrotizing enteritis	In infants, ≥2 signs and symptoms (vomiting, abdominal distention, prefeeding residuals) and no other recognized cause, *and* Persistent microscopic or gross blood in stools, *and* More than one radiologic abnormality (eg, pneumoperitoneum, pneumatosis intestinalis, unchanging rigid loops of small bowel)

*For infants ≤1 yr of age, the symptoms and signs above are adapted to fever (>38°C rectal), hypothermia (<37°C rectal), apnea, bradycardia, or sternal instability.

Primary, first infection; *secondary*, infection as a result of another previous infection in the patient.

Identification, synthesis, interpretation, and report generation of HAI surveillance data in the health care setting are performed by infection control professionals. These professionals have completed certification requirements, have achieved competence in infection prevention and control practice, and have been shown to perform HAI surveillance more accurately than do quality assurance personnel.[22]

Screening

Patient Screening

Screening of patients for colonization with certain antibiotic-resistant organisms (AROs) such as MRSA has been proposed as a method to contain spread of these organisms in colonized or infected patients, although data on its efficacy in reducing clinical infections are mixed.[23,24] Several types of ARO screening programs have been described, including admission screening based on risk factors (eg, hospitalization in the past 6 months, patient from a long-term care facility), universal screening on admission, universal decolonization strategies, and weekly point prevalence screening surveys. The pretest likelihood of colonization, cost of the test, timeliness of test reporting, ability to isolate screened patients, and degree to which ARO transmission is occurring are all factors that influence the feasibility and effectiveness of the screening program chosen. Although increased frequency of screening will identify more colonized patients, it is not clear if this practice reduces the frequency of disease or transmission in the PICU setting. Increasing ARO surveillance can be considered when ARO disease and transmission continues to occur despite the implementation of best practices for prevention.[25]

Visitor Screening

The importance of family-centered care and visitation by siblings, as well as parents,

means that PICUs must establish mechanisms to identify visitors who may have communicable infections before they enter patient care areas. Education of visitors regarding signs and symptoms of illness and recommendations to remain away can be performed with brochures, posters, telephone messages, and videos, for example.

Occupational Health

Occupational health programs play an essential role in the protection of health care workers from infectious diseases through prevention and management of unintended communicable disease exposures. These interventions reduce the risk of infectious occupational hazards to health care workers, as well as opportunities for health care workers to spread infectious diseases to patients. Occupational health programs ensure health care workers are offered immunization against vaccine-preventable infectious diseases of importance in the health care setting, perform fitness-to-work assessments, assist in educational programs so that health care workers can protect themselves and their families from acquiring infectious diseases while at work (eg, respiratory protection programs, respirator fit testing), and provide postexposure counseling and care (eg, blood exposures during phlebotomy, unprotected intubation of a patient with meningococcemia or group A *Streptococcus* toxic shock syndrome).

Selected Topics in Policy, Procedure, and Program Development to Prevent Health Care–Associated Infection

Infection-prevention strategies often fall into two categories: vertical or horizontal. Vertical infection-prevention strategies are based on reducing colonization or infection due to a specific pathogen, under the pretense that it causes the most morbidity or mortality, is most frequent, or is remediable. Horizontal infection-prevention strategies are universal and population based, with major examples being hand-hygiene and care bundles.

Bundles

Care “bundles” are a group of evidence-based interventions that, when executed together, result in better patient care than when implemented individually. Characteristics of care bundles are their scientific grounding, all-or-none implementation (the process is not completed if one step is left out), goal of improved reliability of processes needed for effective care, and potential to contribute to improved teamwork and interprofessional communication in a care area. There is evidence that they can reduce HAIs or colonization.[26,27] Intervention bundles to prevent BSIs and VAP in the ICU setting have been included in national patient safety campaigns such as the United States' Institute for Healthcare Improvement's “Saving 100,000 Lives” and the Canadian Patient Safety Institute's “Safer Healthcare Now.”

Antibiotic Stewardship

Judicious use of antimicrobials is now seen as an essential component of preventing

the emergence of multidrug-resistant organisms and improving individual outcomes.[28] Principles of judicious antibiotic use include restriction of antibiotics (eg, stop orders, restricted hospital formulary, requirement for infectious disease consultation for use of certain drugs), timely antimicrobial susceptibility reporting, and educational efforts aimed at changing physician-prescribing practices (see also Chapter 107).[29]

Antibiotic stewardship begins with empiric treatment of the newly admitted patient. Although a suspected severe infection should initially be treated with broad-spectrum antibiotics, therapy should be changed to the most narrow spectrum agent once culture results are available or discontinued if there is no further evidence of bacterial infection.

Antibiotic cycling refers to a scheduled rotation of antibiotics with similar spectrums of bacterial coverage for a specified period, with the aim of limiting the emergence of resistance to any single agent. Although this strategy has been proposed as a potential method to decrease antimicrobial resistance, there is insufficient evidence to recommend its widespread application at this time, and further clinical studies are required in the PICU context.[30-32]

The clinical pharmacist is an integral member of PICU daily bedside rounds. He or she should participate in the one-on-one education of house staff and nursing, be available for consultation, and assist in the development of evidence-based antibiotic prescribing guidelines based on local epidemiology.

Antibiotic Gastric Decontamination

Normal gut flora have an important role in nutrition, metabolism, and immune regulation. The normal balance of organisms is altered when a child becomes ill or receives antibiotics, leading to infection by endogenous flora. Selective decontamination of the digestive tract was first introduced in 1983 and has been extensively studied in adult ICU patients, demonstrating no effect on resistance patterns and a mortality benefit in some studies.[33,34] Selective decontamination protocols involve a short course of IV antimicrobials (eg, third-generation cephalosporin) and oropharyngeal and enteral nonabsorbable antimicrobials (eg, colistin, amphotericin B, tobramycin) in addition to routine infection control practices. Despite the presence of data in children showing benefit in small randomized controlled trials, use in North America remains infrequent in both adult and pediatric ICUs.[35-37]

Probiotics

An alternate strategy to reduce the development of potential AROs is the oral administration of probiotics (nonpathogenic microorganisms) such as lactobacillus. Their main role appears to be the prevention of pediatric antibiotic-associated diarrhea, prevention of necrotizing enterocolitis in premature infants, and treatment of *C. difficile*–associated diarrhea. Although apparently not associated with harm, the role of probiotics remains unclear in the critically ill child and cannot currently be recommended as a routine management strategy.[38,39]

Specific Health Care−Associated Infection

Syndromes in the Pediatric Intensive Care Unit

Bloodstream Infections

BSIs are usually the most common HAI acquired in the PICU setting and are associated with morbidity, excess length of stay, and mortality, with estimates of attributable costs of up to $16,000 to $39,000 per patient.[40,41] Most BSIs are associated with intravascular catheter use and commensal skin flora that gain access to the bloodstream through the device. The scope of intravascular device–associated infections includes laboratory-confirmed bacteremia, infections of the skin and subcutaneous tissues around the device (exit site and tunnel infections), clinically defined sepsis, septic thrombophlebitis and thrombosis, and right-sided endocarditis. For surveillance purposes, BSIs are categorized as primary (no other identifiable source of infection) or secondary (the BSI occurred as the result of an infection at another site). Surveillance definitions used for CLA-BSI can be found in Table 110.2.

Epidemiology

The pooled mean rate of CLA-BSIs in 293 pediatric medical/surgical ICUs representing more than 400,000 central line days in the 2012 report of the NHSN was 1.4 infections per 1000 central line days, with a 25th percentile of 0.0 and a 90th percentile of 2.9. Rates are similar in cardiothoracic and surgical-specific critical care units. The rates of CLA-BSIs have been rapidly declining over the past decade, being upwards of 4.7/1000 patient days as recent as 2007.[15] The median utilization ratio was 0.46 (central line days per patient days), which is comparable with adult ICUs.

The most common infecting organism in CLA-BSI is the gram-positive bacteria coagulase-negative *Staphylococcus* (CONS), a group of about 20 species including *Staphylococcus epidermidis,* that are normal flora of human skin. Gram-negative bacteria, including Enterobacteriaceae, and nonfermenting gram-negative bacteria such as *Pseudomonas* spp., *Acinetobacter* spp., and *Stenotrophomonas* spp., account for about 25% of infections. *Candida* spp. infections are increasingly recognized.[42]

There are many types of intravascular devices, including central venous catheters (CVCs), arterial catheters, and peripherally inserted catheters, all of which are associated with infection. Catheters can also be classified according to the site of insertion, expected duration of placement (eg, long vs. short term), and path to the vessel (eg, tunneled or not). To date, surveillance for HAI associated with these devices has focused on central venous lines. However, with rates of infection of arterial catheters in adult studies comparable to those for pediatric central lines, these must be monitored appropriately.[43]

Prevention

Successful programs to reduce the incidence of CLA-BSIs have been reported in the past decade; all use multimodal team-based, systematic approaches in which combinations of effective preventive interventions are introduced into a care setting.

The central line bundle is a combination of eight components broken into two separate bundles for insertion and maintenance. The bundle components described in the following sections are from the Canadian Safer Healthcare Now campaign and align with other improvement bundle packages for reduction of CLA-BSIs, and they

have been proven effective in substantially reducing CLA-BSI incidence.[44]

The insertion bundle components include hand hygiene, maximal barrier precautions, and skin antisepsis. Maximal sterile barrier precautions for the inserter mean strict compliance with hand hygiene, a cap that covers all hair, a mask that covers the mouth and nose securely, a sterile gown, and sterile gloves. The patient is covered from head to toe with a sterile drape except for a small opening for the insertion site and to maintain the airway. Chlorhexidine skin antisepsis is recommended over other antiseptic agents. With regard to the optimal site for a line, practitioners are urged to consider what is best for the patient on the basis of current and future needs, anatomic features, and the inserter's technical competence.

Other components of success include empowering nurses to enforce the use of a central line checklist that incorporates inclusion of all components of the insertion bundle and constraining practice by creating central line insertion kits or carts that include the required equipment needed to maintain asepsis (eg, only one antiseptic offered: chlorhexidine).

Antibiotic-impregnated CVCs are not recommended for routine use unless the concerted efforts to implement a strategy fail to reduce a local institution's infection rates below benchmark levels. They may be considered in specific patient populations such as the immunosuppressed requiring long-term CVC use, although their superiority over standard CVCs in this population has never been proven.

Ultrasound guidance for insertion of CVCs to reduce insertion-related complications has become the standard of care for the past decade (see also Chapter 20). The associated temporal decrease in insertion-related complications might contribute to a reduction in CLA-BSIs through less traumatic catheter placement, but this remains to be proven.

The maintenance bundle to prevent CLA-BSIs incorporates, in addition to hand hygiene, multimodal education and training programs, aseptic access to the lumens (scrubbing the hub), regular checks of the entry site for inflammation with each dressing change (at minimum), daily review of line necessity with removal if deemed unnecessary, and a dedicated total parenteral nutrition line.

Emerging trends in maintenance of CVCs include chlorhexidine-impregnated transparent dressings and disc (which hug the catheter at the insertion site) and are intended to reduce the quantity of bacteria at the skin entry site.[45] Daily chlorhexidine bathing has been shown in one study to reduce bacteremia in critically ill children, although this has yet to be widely adopted, with recent pragmatic adult studies showing no benefit.[46,47]

Practitioners are urged to check for recent updates in CLA-BSI reduction quality improvement strategies from Safer Healthcare Now (www.saferhealthcarenow.ca) or the Institute for Healthcare Improvement (www.ihi.org) or their national or local equivalents, as optimal strategies change over time on the basis of evolving evidence.

Management

The diagnosis of BSI is based only on clinical signs and symptoms and is insensitive and nonspecific.[48] Microbiologic confirmation should be sought and broad-spectrum antimicrobial therapy initiated early and targeted at likely pathogens until results are available. If the device is suspected to be the source of infection or to have been secondarily infected, the clinician will need to decide if the infection can be

eradicated with the device in place. The need for catheter removal will depend on the infecting organism and the availability of another route for parental access and antibiotic administration. Although coagulase-negative *Staphylococcus* (CONS) infections can often be treated without catheter removal, this is difficult if the infection is due to fungal infection or infection with *Pseudomonas* spp. or *S. aureus*.[49] The possibility of secondary seeding of the heart or thrombophlebitis should also be considered during decision making.

Respiratory Infections and Ventilator-Associated Pneumonia

Respiratory Infections

Respiratory infections acquired during health care encompass a broad range of illness of the upper and lower respiratory tract (see Table 110.2). In the child with high-acuity illness requiring admission to the PICU, some respiratory infections are particularly associated with increased morbidity, mortality, and health care cost. The following section focuses on viral respiratory tract infections, VAP, and sinusitis.

Epidemiology

Surveillance for hospital-acquired viral respiratory illness is infrequently reported, although the burden of disease is likely substantial.[50] Hospital-acquired RSV is associated with prolonged length of stay, hospital costs, and increased morbidity and mortality rates.[45,51,52]

Like RSV, influenza virus HAI occurs at the same time as the local winter community epidemic. Coronaviruses such as SARS and MERS-CoV have caused nosocomial transmission in Canada, Asia, and the Middle East, causing large morbidity and mortality among patients and health care providers.[53,54]

Respiratory viral illness can increase the risk of secondary bacterial infection because the normal defensive function of the mucociliary apparatus is impaired and colonizing bacteria in the respiratory tract can invade through the nasopharynx or descend to the lower respiratory tree.

VAP is the second most common HAI in the PICU. In the most recent NHSN report pooling data from 132 pediatric medical-surgical ICUs, the pooled mean incidence was 0.8 episodes of VAP per 1000 ventilator days.[55] Notably, the rate of VAP has decreased in the past decade from mean rates of 2.9 per 1000 ventilator days in 2002.[56] VAP is a serious and life-threatening complication of PICU admission and is associated with prolonged ICU stay, need for ventilatory support, excess costs, and increased mortality.[57]

VAP is usually due to endogenous bacteria, and less commonly fungi, from the patient's oropharynx. It is often categorized into early (<5 days after intubation) and late (>5 days after intubation). Early VAP is usually caused by normal endogenous flora of the respiratory tract such as *Haemophilus influenzae, Moraxella* spp., *Streptococcus pneumoniae,* and alpha-hemolytic *Streptococcus* spp. During hospitalization, the normal endogenous flora of the nasopharynx are replaced within days by gram-negative bacteria such as *Pseudomonas* spp., *Escherichia coli, Acinetobacter,* and *Stenotrophomonas* spp., as well as various *Enterobacteriaceae* spp. or *S. aureus*. For practical reasons, many studies base their laboratory diagnosis on

specimens obtained from the endotracheal tube rather than invasive sampling of the lower respiratory tract; hence isolated microorganisms could be present in the nasopharynx, colonizing the endotracheal tube, or actually be the cause of infection in the lung.[58]

In addition to its role as a conduit, the endotracheal tube also serves as a foreign body. As with other devices, an endotracheal tube interferes with normal defense mechanisms (eg, cough, mucociliary apparatus) and acts as a nidus for adherence of microorganisms, which create a biofilm. Tracheal suctioning can cause mucosal denudation and detachment and aspiration of adherent biofilm aggregates that become a pulmonary inoculum. Not surprisingly, the length of respiratory assistance and endotracheal intubation—and therefore the device-related risk—remain significant risk factors of nosocomial pneumonia.[59] Other risk factors for HAI pneumonia include immune deficiency, use of neuromuscular blocking agents, reintubation, transport outside the ICU, multiple organ dysfunction, shock, multiple-organ trauma, severe head trauma, and burns.[60-62]

Prevention

Respiratory Viruses

Prevention of HAI respiratory virus infection in the PICU can be accomplished through a collaborative effort between the PICU and the organization's infection prevention and control and occupational health programs. The goal of this effort is to avoid contact between persons with probable or definite respiratory infection (including family members) and PICU patients, with prompt institution of isolation practices in symptomatic patients, regardless of laboratory confirmation.

Occupational health programs assess fitness-to-work in health care workers with possible respiratory illness. An employee with new-onset cough and rhinorrhea, for example, could be deployed to a non–patient care assignment rather than the PICU or sent home. The occupational health program should ensure immunization status for employees is current and offer annual influenza vaccine programs.

As part of the hospital and PICU admission process, screening of the patient for symptoms and signs of infectious illness should be conducted to determine appropriate placement. In the winter respiratory season, screening of all children for viral infections and placing them in isolation until results are available have been reported to limit nosocomial spread, with tests available for a variety of respiratory viruses.[63]

Ventilator-Associated Pneumonia

Strategies of prevention are directed against the three mechanisms by which VAP is thought to occur: aspiration of secretions, colonization of the aerodigestive tract, and use of contaminated equipment. General recommended measures are to conduct active surveillance for VAP, minimize the duration of ventilation and use noninvasive ventilation whenever possible, perform daily assessments of readiness to wean/discontinue mechanical ventilation, and educate health care workers who care for ventilated patients about VAP. The Society for Healthcare Epidemiology of America publishes VAP-prevention guidelines, including pediatric specific discussions.[64]

Specific precautions of the pediatric VAP bundle are hand hygiene before and

after circuit manipulation, elevation of the head of the bed (angle varies based on positioning limitations of the child based on age), proper positioning of the oral or nasogastric tube, elimination of the routine use of instillation before suctioning of the endotracheal tube, changing in-line suctioning catheters only when visibly soiled or malfunctioning, regular oral care for all children, and maintaining the ventilator tubing in a dependent position. Adolescent patients are recommended to use endotracheal tubes with subglottic secretion drainage for high-risk patients who are likely to require intubation for longer than 72 hours.[65]

The strategies to prevent VAP highlight practical recommendations, with not one specific intervention found to be effective; rather, a bundle of care and maintained vigilance are the most effective tools in VAP prevention.

Management

The management of RSV infection in the PICU is mainly supportive. Influenza infection can be treated with neuraminidase inhibitors (oseltamivir, zanamavir), which shorten the duration of fever and improve outcomes in critically ill children.[66,67]

Ventilator-Associated Pneumonia

VAP is difficult to diagnose accurately because of the inaccessibility of the lower respiratory tract. The gold standard for diagnosis is microbiologic confirmation from a lower respiratory tract specimen, such as lung biopsy. Obtaining uncontaminated lower respiratory tract specimens in children by bronchoalveolar lavage, lung biopsy, and transthoracic biopsy are procedures with inherent risks.[68,69] Despite the accepted shortcomings, tracheal aspirates remain the most common specimen for guiding initial empiric antibiotic therapy in a child with suspected VAP. There is often poor correlation between tracheal aspirate microbiology and bronchoalveolar microbiology.[58] Recent changes in adult definitions of VAP have expanded the term to ventilator-associated events to more effectively and objectively capture complications of ventilation, including pneumonia. These changes have yet to apply to children, although this is likely forthcoming.

Aggressive and prompt treatment is required when nosocomial pneumonia is suspected in a critically ill patient. Initial empiric therapy for VAP should be broadly based, with consideration of local microbiologic data on antibiotic resistance and a plan to reevaluate and narrow antibiotic selection when results of cultures or other diagnostic information is available. If aspiration is suspected, coverage for anaerobes can be considered (eg, ticarcillin-clavulanate or clindamycin). If methicillin-resistant *S. aureus* is suspected, vancomycin or linezolid should be used. The appropriate duration of therapy for VAP in children is not known, with most experts recommending a 5- to 10-day course of therapy.

Sinusitis

Although acute sinusitis (inflammation of the nose and paranasal sinuses) is a common infection in childhood, data on its occurrence in the PICU are scarce.[70] Studies in adults have shown an increased risk of sinusitis in nasotracheal intubations, with prolonged nasal cannulation associated with increased incidence of sinusitis in older children and adults. Studies have also indicated that larger nasal

cannulae appear to accelerate this process and that fewer devices in the nose decrease risk of infection.[71-73] When the diagnosis is based on computed tomography (CT) imaging, however, it can be observed in up to 70% of ventilated patients; the clinical relevance of this finding remains undetermined.[70] Active surveillance for this HAI is not done by most programs.

Sinusitis can be categorized as acute or subacute bacterial, recurrent acute bacterial, chronic, or acute on chronic in nature. Although the ethmoid and maxillary sinuses are present at birth, the sphenoid and frontal sinuses are not pneumatized until age 5 and 7 years, respectively. Diagnosis of sinusitis is challenging in children, particularly in the intubated child. Direct sinus puncture to permit microbiologic identification of infecting organisms is the gold standard for diagnosis, although it is rarely performed. Normal sinus radiographs and CT scans provide evidence that sinusitis is absent, but mucosal thickening is a nonspecific finding. The surveillance definition of health care–associated sinusitis is seen in Table 110.2.

Acute sinusitis is most commonly caused by respiratory flora such as *S. pneumoniae, H. influenzae,* and *Moraxella* spp. In ventilator-associated sinusitis, *S. aureus, Pseudomonas aeruginosa,* enteric gram-negative bacilli, and streptococcal infection also need to be considered, and it is often coincident with VAP.

Prevention

The paranasal sinuses are contiguous with the nasopharynx and mostly lined with pseudostratified ciliated respiratory epithelium. The normal defense of the sinuses against infection is the mucociliary apparatus. Factors that would be expected to predispose to sinus obstruction or decreased mucociliary function include foreign bodies in the nasopharynx (eg, nasogastric or endotracheal tubes), previous viral respiratory infection, preexisting abnormalities such as cilial disorders or cystic fibrosis, and craniofacial anatomic abnormalities or facial trauma. Orotracheal intubation is recommended over nasotracheal intubation in older children because the latter may increase the risk of sinusitis. Judicious use of antibiotics in the ICU would be expected to decrease the risk of colonization of the respiratory tract with gram-negative and antibiotic-resistant organisms.

Management

Because of their proximity to the brain, bacterial or fungal infection of the sinuses may be complicated by contiguous spread. Systemic antimicrobial therapy should be directed broadly to cover anaerobic respiratory flora, gram-positive and gram-negative bacteria such as *Pseudomonas* spp., and enteric flora. Options for antibacterial coverage include a third-generation cephalosporin or monobactam or an extended-spectrum penicillin–clavulanic acid combination with the addition of vancomycin to cover MRSA or penicillin-resistant pneumococcus, depending on local antimicrobial susceptibility and epidemiology.

An otolaryngologist should be consulted in the care of children with complicated sinusitis to determine if surgery is necessary to remediate ostial obstruction or drainage of abscesses. Involvement of the CNS requires neurosurgical intervention. The infectious disease team should also be involved to assist in determining optimal antibiotic combinations and duration of therapy in complicated cases with CNS involvement.

Urinary Tract Infections

The spectrum of illness associated with urinary tract infection (UTI) in the PICU can range from asymptomatic bacteriuria in the presence of a catheter to a funguria that becomes a source of life-threatening disseminated fungal infection.

Epidemiology

A mean of 2.7 catheter-associated UTIs (CA-UTIs) occurred per 1000 catheter days in the US National Health Safety Network surveillance system, with 268 pediatric medical-surgical ICUs reporting in 2012.[55] This rate is less than the 4.0 infections per 1000 urinary catheter days determined 10 years earlier,[56] although compared with CLA-BSI and VAP, the declines over recent years have been less robust (see Fig. 110.1).

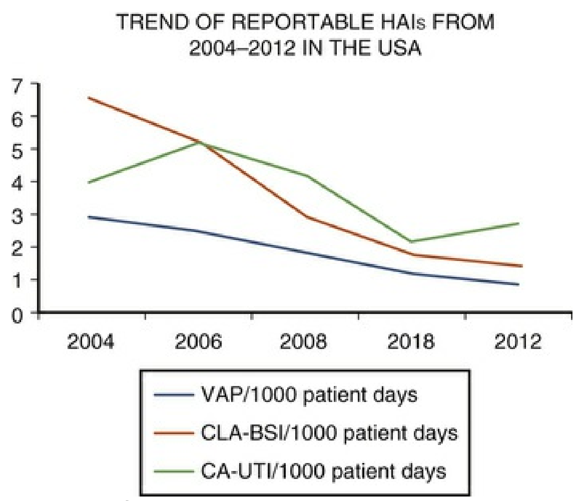

FIG. 110.1 Trend of ventilator-associated pneumonia, central line−associated bloodstream infections, and catheter-associated urinary tract infections from 2004−2012. (From National Healthcare Safety Network, 2012 report. Available at: http://www.cdc.gov/nhsn/dataStat.html.)

A urinary catheter is both a foreign body in the urinary tract and a conduit for microorganisms to ascend to the bladder, ureters, kidneys, and potentially to the bloodstream. Voiding is an important defense mechanism for the urinary tract in which periurethral flora are flushed out regularly. Because of the urethra's anatomic location in the perineum, the most common organisms causing community and health care–associated UTI are normal periurethral or perirectal flora such as *E. coli* and *Klebsiella pneumoniae.* However, Enterobacteriaceae such as *Pseudomonas* spp. and opportunistic organisms such as *S. aureus, S. epidermidis,* and *Candida* spp. can also be involved.

In addition to the general factors that increase risk for HAI in the PICU, children at increased risk for UTI include those with preexisting uropathies, especially neurogenic bladder.

Prevention

Guidelines for the prevention of CA-UTI in acute care hospitals focus on certain key

strategies, all related to urinary catheter use: (1) recommendations for which patients should receive indwelling urinary catheters, (2) recommendations for catheter insertion, (3) recommendations for catheter maintenance, and (4) quality improvement programs and daily reminders to achieve appropriate placement, care, and removal of catheters.[74] The most important action that PICU staff can take to prevent CA-UTIs is to limit the use of urinary tract instrumentation, particularly indwelling urinary catheters. Systemic morphine infusions are not a contraindication to the removal of the urinary catheter.

Proper technique for catheter insertion includes hand hygiene before and after any manipulation of the device, use of aseptic technique, use of the smallest bore catheter needed, and proper securement of the catheter after insertion to prevent movement. The catheter should be maintained as a closed drainage system with unobstructed urine flow. The catheter and collecting system should be replaced if the system is disconnected or leaks occur. Standard Precautions should be used for any manipulation of the catheter or collecting system (eg, use of gloves and gowns as appropriate). Neither systemic antimicrobials, bladder irrigation with antimicrobials, nor complex drainage systems with antiseptics are recommended to prevent CA-UTIs. Special catheter materials (eg, antimicrobial impregnation) are only recommended if a comprehensive strategy to reduce CA-UTI rates is unsuccessful.

Management

Surveillance definitions for UTI acquired in the health care setting are found in Table 110.2. Of note, infection may be asymptomatic or symptomatic. In the critically ill PICU patient, diagnosis of UTI may be difficult because of inability to determine symptoms and signs; therefore laboratory criteria from aseptically obtained urine specimens are essential, with specific criteria for infection available.

For CA-UTI, the catheter should be removed as soon as possible. Once removed, intermittent catheterization may be required if spontaneous voiding does not occur. Therapy should be the narrowest spectrum agent that will treat the offending pathogen; appropriate empiric choices before availability of antimicrobial susceptibility should include consideration of common infecting organisms in that PICU, with appropriate initial choices including an extended-spectrum penicillin or a third-generation cephalosporin.

Skin and Surgical Site Infections

The integument is the largest organ in the human body; it is a barrier to invasion of microorganisms and plays a role in thermal regulation and fluid homeostasis. Disruption of the skin, whether by surgery, insertion of biomedical devices, or pressure sores, interrupts a key defense against infection.

Although almost all surgical procedures are performed in the operating room, a substantial component of care in the PICU is postoperative care for critically ill children. Procedures may also need to be performed in the PICU in patients who are too unstable for transport to the surgical suite or do not have primary closure of the surgical wound. The surveillance definition of skin and surgical site infections (SSTIs) is in Table 110.2.

Epidemiology

The incidence of SSTIs is 1.8% of all pediatric surgical procedures from a recent administrative database and represents less than 10% of HAIs in PICUs.[1,75] In adults, they are now the most common and costly HAI.[76] Complications of SSIs include contiguous or systemic spread and, in adults, an increased length of stay of 7 to 10 days and increased risk of death.

Most commonly, the source of infection is the patient's own flora that migrate into the wound, but other sources include the surgical staff and contaminated instruments. *S. aureus* is the most common pathogen in SSIs without biomedical device placement, but *P. aeruginosa* and other gram-negative bacteria can be isolated. Often a single microbiologic cause is not identified because the surgical site is open and contiguous with skin or mucosa. In procedures in which a device is implanted (eg, neurosurgical cerebrospinal fluid shunts), the most common organism isolated is CONS. Of growing importance are infections caused by multidrug-resistant organisms, such as MRSA, and fungi.

Risk for an SSI can be predicted in adult patients by using the National Nosocomial Infections Surveillance System index, which combines the traditional four-category wound classification system of clean, clean-contaminated, contaminated, and dirty or infected with the American Society of Anesthesiology score and duration of procedure time.[77] An equivalent validated scoring system to identify high-risk children has not been developed. Multiple variables associated with increased risk for SSI in various studies include intrinsic factors (eg, age, glucose control, obesity/malnutrition, smoking, steroid use, prolonged preoperative hospital stay, preoperative nares colonization with *S. aureus,* perioperative transfusion and immunosuppressive medications, presurgical comorbidity) and extrinsic factors (eg, preoperative antiseptic showering, preoperative hair removal, patient skin preparation in the operating room, preoperative hand/forearm antisepsis, management of infected or colonized surgical personnel, antimicrobial prophylaxis). In pediatric cardiac surgery patients, an open sternum is a risk factor for SSIs, with 13% of children with delayed sternal closure developing an SSI in a recent series.[78] Operative risk factors are surgical scrub by the team, skin preparation of the patient, appropriate and timely antibiotic prophylaxis, surgical drapes and attire, surgeon skill and technique, asepsis, and operative time. Operating room characteristics are also considered extrinsic factors. They include ventilation, traffic, and sterilization of surgical equipment. Postoperative factors incorporate incision care and discharge planning.

Prevention

Prevention of SSIs is directed at addressing the clinical variables that increase the probability of infection, as previously mentioned. For example, patient skin preparation, health care worker hand hygiene, and antimicrobial prophylaxis affect the inoculum of bacteria into the wound. Optimal glucose and temperature control enhance the capacity of the host to deal with invading organisms. Recommendations for the prevention of SSTIs are available and updated frequently.[77]

Most SSI bundles include measures to improve timing and choice of antimicrobial prophylaxis, appropriate hair removal, and prospective surgical wound infection surveillance with provision of feedback to individual surgeons. The surveillance definitions for SSI are provided in Table 110.2.

A considerable body of research has demonstrated that perioperative antibiotic

prophylaxis is most effective when given 1 hour before the incision to maximize tissue concentration during cut time—when the antibiotic (as narrow spectrum as possible and as short a course as possible) is active against the likely contaminating organisms. Although the duration of administration varies by procedure, the optimal duration ranges from the immediate perioperative period to the 24 hours after the surgery. Doses beyond this interval do not prevent infection and put the patient at risk of developing infections with resistant bacteria and fungi. The choice and duration of antibiotic prophylaxis depend on the surgical procedure, degree of wound contamination, emergency or elective surgery, and patient allergy.

Postoperative surgical site care includes regular observations and documentation of the integrity of the site. Recommendations for postoperative incision care include protecting a primary closure incision with a sterile dressing for 24 to 48 hours postoperatively, adhering to hand hygiene principles, applying sterile technique when changing dressings, promoting proper incision care, and identifying complications by educating patients and families.[77]

Management

Recognition of SSIs requires regular wound inspection for the usual signs of inflammation, with or without pus. Microbiologic confirmation of infection is often not useful because of contamination of the operative site by contiguous external surfaces. Treatment of SSIs includes appropriate empiric antimicrobials directed at the likely infecting organisms and subsequent narrowing of the spectrum if organism identification and susceptibility are available. Drainage of the infected area should be facilitated (eg, removal of staples), wound debridement may be required, and foreign bodies may need to be removed. The extent of the infection will determine the wound care requirements, which may involve packing the wounds or use of negative pressure wound therapy.

Ventriculostomy-Related Infections

The incidence of ventriculostomy-associated infection varies widely in the literature and is influenced by both patient characteristics and system factors, such as infection control policies and procedures pertaining to placement and maintenance of external ventricular drains. The risk increases with increasing duration of catheterization and with repeated insertions, but routine replacement is not recommended. The use of local antibiotic irrigation or prophylactic systemic antibiotics is not recommended. Routine surveillance cultures of cerebrospinal fluid are not more likely to detect infection than are cultures obtained when clinically indicated.[79]

Hospital-Associated Diarrhea

C. difficile–associated diarrhea is a potentially life-threatening illness that can range in clinical presentation from diarrhea to colitis and megacolon. Children, especially those younger than 5, are often asymptomatic carriers and likely have other causes of symptoms, especially in those younger than 5 years of age. However, it can cause problematic illness in immunosuppressed patients and pediatric practitioners should be familiar with its diagnosis and management. Outbreaks of rotavirus and norovirus can occur in critical care settings, where close health care worker/patient

contact can facilitate spread of secretions. Prevention of diarrheal illness is accomplished by prompt isolation of patients with diarrhea before laboratory results are available, careful hand hygiene, and regular and thorough environmental cleaning focusing on high-touch surfaces.

CHAPTER 111

Sepsis

Matthew N. Alder, Mary Sandquist, Hector R. Wong

PEARLS

- The typical patient with septic shock has simultaneous derangements of cardiovascular function, intravascular volume status, respiratory function, immune/inflammatory regulation, renal function, coagulation, hepatic function, and/or metabolic function.
- The complexity and heterogeneity of septic shock warrant a systematic and multifaceted approach on the part of the pediatric intensivist.
- Although some overlap exists among the terms spanning the sepsis spectrum (systemic inflammatory response syndrome, sepsis, severe sepsis, and septic shock), each term is intended to define a particular patient population.
- Sepsis is now viewed as a dysregulation of the immunologic and inflammatory pathways normally directed toward pathogen eradication and restoration of homeostasis.
- From a clinical standpoint, the treatment of sepsis entails four important goals: initial resuscitation, pathogen eradication, maintenance of oxygen delivery, and (in the future) carefully directed modulation of the inflammatory response.
- Genomic medicine and systems biology represent novel approaches for studying complex processes such as septic shock.
- The development of robust stratification and phenotyping strategies has the potential to more effectively manage the intrinsic heterogeneity of septic shock and thus improve the effectiveness of both clinical research and individual patient care.

Introduction

Management of the patient with septic shock embodies the discipline of pediatric critical care medicine. The typical patient with septic shock has simultaneous derangements of cardiovascular function, intravascular volume status, respiratory function, immune regulation, renal function, coagulation, hepatic function, and/or metabolic function. The degree to which any one of these derangements manifests in a given patient is highly variable and influenced by multiple host and nonhost factors, including developmental stage, presence or absence of comorbidities,

causative agent of septic shock, immune status, genetic background, and variations in therapy. These factors combine to profoundly influence the course and ultimate outcome of septic shock.

The complexity of septic shock warrants a systematic and multifaceted approach on the part of the pediatric intensivist. Optimal management requires a strong working knowledge of not only cardiovascular physiology and infectious diseases but also multiple organ function and interaction, inflammation-related biology, immunity, coagulation, pharmacology, and molecular biology. The pediatric intensivist will also need a working knowledge of genomic medicine for the future management of patients with septic shock. This chapter provides a comprehensive description of the many aspects influencing the development and outcome of septic shock, pathophysiology at the physiologic and molecular levels, contemporary management of septic shock, and what the authors believe to be the next important future directions in the field. Ultimately, this information must be integrated with bedside experience and clinical acumen, which cannot be supplanted by a book chapter.

Epidemiology

A true picture of the epidemiology of septic shock is clouded by the lack of a reliable case definition. This is true for both the adult population and pediatric population. A few pediatric-specific studies, however, illustrate the importance of sepsis in today's modern ICU. Proulx et al.[1] analyzed the incidence and outcome of the systemic inflammatory response syndrome (SIRS), sepsis, severe sepsis, and septic shock (see next section for definitions) in a single institution. A total of 1058 admissions were analyzed over a 1-year period. SIRS was present in 82% of patients, 23% had sepsis, 4% had severe sepsis, and 2% had septic shock. The overall mortality rate for this patient population was 6%, with the majority of deaths occurring in patients with multiple organ dysfunction syndrome (MODS). Among the patients with MODS, distinct mortality rates were associated with SIRS (4%), sepsis (22%), severe sepsis (25%), and septic shock (52%). Later studies by Watson et al.[2] provide the most comprehensive retrospective epidemiologic surveys of pediatric sepsis to date. By linking 1995 hospital records from seven large states (representing 24% of the United States population) with census data, they estimated an annual incidence of 42,371 cases of severe sepsis in individuals younger than 20 years of age (0.6 cases/1000 population). The highest incidence was in neonates (5.2 cases/1000 population), compared with children ages 5–14 years who had an incidence of 0.2 cases/1000 population. The overall mortality rate in this population was 10.3% (4364 deaths per year nationally). In addition, patients younger than 1 year of age and patients with comorbidities had higher mortality rates than patients between 5 and 14 years old and patients without comorbidities, respectively. Their study also estimated an annual national health care cost of $1.7 billion associated with severe sepsis.

In a follow-up study, these investigators used a similar approach to investigate severe sepsis trends in the United States from 1995–2005.[3] They reported an overall decrease in the case-fatality rate over this period, from 10.3%–8.9%, but an overall increase in the prevalence of severe sepsis. Most of this increase was accounted for by an increase in the prevalence of severe sepsis in newborns.

Czaja et al.[4] used the discharge diagnosis of severe sepsis for Washington State to

investigate the readmission rates and late mortality for children (1 month to 18 years old) following severe sepsis. From 1990 through 2004, 7183 children were diagnosed with severe sepsis and 6.8% of these patients died during the sentinel admission or within 28 days of discharge. Importantly, death certificates confirmed that an additional 434 (6.5%) of the initial survivors died during the follow-up period with the highest late death rate occurring within 2 years of the initial hospitalization. Although most of the early and late deaths occurred in children with comorbidities (8% early death, 10.4% late death), 8% of children with no comorbidities died during their initial hospitalization with 2% of the 28-day survivors being classified as late deaths.

Schlapbach et al.[5] recently reported on the epidemiology of invasive infections, sepsis, and septic shock in critically ill children in Australia and New Zealand. The age-standardized incidence increased every year, from 2002–2013, for all three study categories. Critically ill children with invasive infections, sepsis, or septic shock accounted for 26% of all pediatric deaths among all the critically ill children in this cohort. Comparing 2008–2013 with 2002–2007, risk-adjusted mortality significantly decreased for invasive infections and sepsis, but not for septic shock. In 2015, Weiss et al.[6] published the first international, prospective epidemiologic study of pediatric severe sepsis. Almost 7000 patients younger than 18 years of age were screened on 5 days from 2013–2014 at 128 sites from 26 countries using a point prevalence study method. Severe sepsis was defined using the 2005 International Pediatric Sepsis Consensus Conference criteria.[7] This large, comprehensive study demonstrated an 8.2% prevalence of pediatric severe sepsis in international pediatric ICUs (95% CI 7.6, 8.9%), consistent with adult epidemiologic data. Hospital mortality was 25% regardless of age or country. Multiorgan dysfunction was demonstrated in 67% of patients at sepsis recognition with 30% subsequently developing new or progressive multiorgan dysfunction.

Collectively, these data illustrate that sepsis continues to present a major pediatric public health problem in terms of incidence, mortality, and health care costs. Nevertheless, there is an ongoing need for quality epidemiologic studies of sepsis in children. Quality epidemiologic studies are necessary for the understanding of not only incidence but also the impact of new knowledge and therapies. One major issue that must be addressed is the development of more meaningful and consistent case definitions. Consistent case definitions will also facilitate and improve the design of more effective interventional trials specific to the pediatric population. Equally important is objectively measuring long-term outcomes in these patients (ie, quality of life) beyond the dichotomy of "alive" or "dead." Progress in this important area is steadily coming to fruition.[8-11]

Definitions

Intuitively, the experienced pediatric intensivist knows when he or she encounters a patient with sepsis. Thus strict definitions of sepsis and septic shock could be viewed as having relatively limited value in daily practice. Despite this common perception, there is a clear need for standard definitions of sepsis and septic shock for three primary reasons. First, with the development of standard definitions, clinicians will be able to more accurately characterize the epidemiologic features of septic shock in the pediatric population. Second, as novel, expensive, and potentially higher-risk

therapies are developed, it will be important to accurately identify and stratify patients early in the course of sepsis if clinicians are to apply those therapies to the most appropriate groups and realize a more favorable benefit-to-risk ratio in a given patient population. Finally, standard definitions are crucial to the design of much needed, pediatric-specific interventional trials.

The International Consensus Conference on Pediatric Sepsis and Organ Dysfunction was convened in 2002 to develop pediatric-specific definitions for systemic inflammatory response syndrome (SIRS), sepsis, severe sepsis, septic shock, and organ failure, and the results of this conference were subsequently published.[7] The standard terms to describe the sepsis spectrum are SIRS, sepsis, severe sepsis, and septic shock. Each term is intended to describe a clinical syndrome having increasing illness severity and relatively increasing specificity, which in turn drives important clinical decision and therapeutic processes.

SIRS is not a diagnosis. The term is intended to represent a state of relative inflammatory/immune activation in a given patient and is said to be present when a patient meets at least two of the four criteria listed in Box 111.1, one of which must be abnormal temperature or abnormal leukocyte count. Thus patients with diverse clinical conditions, such as sepsis, pancreatitis, burns, or hypermetabolism following major trauma or surgery, can meet criteria for SIRS. Sepsis is defined as SIRS secondary to an infection, either documented by microbiology cultures or in the presence of other clinical evidence of infection. Severe sepsis is defined by sepsis criteria plus either cardiovascular dysfunction or acute respiratory distress syndrome or at least two other dysfunctional organ systems. Septic shock is defined by sepsis criteria, plus cardiovascular dysfunction. Importantly, each criterion takes into account the influence of developmental age on physiologic variables. The reader is referred to the original publication by Goldstein et al.[7] for further details and definitions of organ dysfunction. At the time of this writing, it is anticipated that a consensus conference will be convened to update the definition of pediatric sepsis.

Box 111.1

Criteria for Systemic Inflammatory Response Syndrome

The presence of at least two of the following four criteria, one of which must be abnormal temperature or leukocyte count:

1. Core temperature (rectal, bladder, oral, or central catheter) >38.5°C or <36°C.

2. Tachycardia, defined as a mean heart rate >2 standard deviation above normal for age in the absence of external stimulus, chronic drugs, or painful stimuli; otherwise unexplained persistent elevation over a 0.5- to 4-hour time period; for children <1 year old: bradycardia, defined as a mean heart rate <10th percentile for age in the absence of external vagal stimulus, β-blocker drugs, or congenital heart disease; or otherwise unexplained persistent heart rate depression over a 0.5-hour time period.

3. Tachypnea, defined as mean respiratory rate >90th percentile for age, or the need for mechanical ventilation for an acute process not related to underlying neuromuscular disease or the receipt of general anesthesia.

4. Leukocyte count elevated or depressed for age (not secondary to chemotherapy-induced leukopenia) or >10% immature neutrophils.

Clinical Presentation

As a syndrome potentially affecting the entire body, the clinical presentation of sepsis is highly heterogeneous. The most common clinical manifestations of sepsis include fever or hypothermia, tachypnea, tachycardia, leukocytosis or leukopenia, thrombocytopenia, and change in mental status. It should be noted, however, that in the absence of meningitis, changes in mental status are relatively late manifestations of septic shock and should not be relied on for early recognition of shock. One of the earliest signs alerting caregivers to the possibility of infection is fever. A number of the cytokines elicited in response to infection are pyrogens, particularly interleukin (IL)-1β and tumor necrosis factor (TNF)-α. Patients can also exhibit hypothermia, which is more common in infants than older children. Finally, petechiae and pupura can be present and are potentially ominous signs of purpura fulminans.[12]

Shock states can be grouped into four broad categories: hypovolemic, cardiogenic, obstructive, and distributive shock (see also Chapter 36). Septic shock is unique because all four forms of shock may be involved simultaneously. The patient may have hypovolemic shock resulting from capillary leak, increased insensible water losses, poor intake, and/or decreased effective blood volume secondary to venodilation and arterial dilation (ie, increased vascular capacitance). Cardiogenic shock manifests as depressed myocardial contractility and low cardiac output secondary to myocardial-depressant effects of bacterial toxins and inflammatory cytokines. Obstructive shock can result indirectly from diffuse microvascular thrombosis or directly from abdominal compartment syndrome. Distributive shock can result directly from abnormally low systemic vascular resistance, leading to maldistribution of blood flow, or indirectly from the inability of tissues to adequately use oxygen at the mitochondrial level (ie, cytopathic hypoxia).

The degree to which an individual patient manifests these physiologic perturbations is highly variable. In some cases, patients display increased cardiac output with diminished systemic vascular resistance. The presenting symptoms in this type of patient are tachycardia, a hyperdynamic precordium, bounding pulses, wide pulse pressure, and warm, flushed skin characteristic of the distributive mode of shock or the so-called “warm” shock state. Despite this clinical appearance, the perfusion of major organs during warm shock may remain highly compromised secondary to maldistribution of blood flow. Alternatively, a patient with depressed cardiac output and elevated systemic vascular resistance has cool, mottled skin with diminished pulses and poor capillary refill characteristic of the “cold” shock state. Limited data and our collective anecdotal experience suggest this latter presentation, cold shock, is more common in younger children compared with teenagers and adults.[13] It has been suggested that patients who develop community-acquired septic shock more commonly present to the ICU with signs of “cold” shock, whereas patients who develop septic shock secondary to catheter-related infections more commonly present to the ICU with signs of “warm” shock.[14] It is important to recognize that a given patient may transition from one shock state to another, and recognition and reassessment of these classes of shock are absolutely central to the choice of cardiovascular medications.

Patients with sepsis often have presenting symptoms of respiratory abnormalities, including tachypnea and hypoxia. Tachypnea alone can reflect a compensatory, respiratory alkalosis aimed at counteracting a metabolic acidosis secondary to shock. Chest roentgenogram in this setting often reveals a relatively small cardiac silhouette (potentially reflective of relative hypovolemia) with few vascular markings. However, in the face of capillary leak and decreased myocardial function, patients with septic shock often develop pulmonary edema and acute respiratory failure as fluid resuscitation proceeds. Alternatively, respiratory abnormalities can reflect pneumonia as the primary source of infection and/or the development of acute respiratory distress syndrome (ARDS). In these situations chest roentgenography will display patterns of pulmonary infiltrates characteristic of the respective scenarios.

All organ systems can be adversely affected by poor perfusion and decreased oxygen delivery. In addition, all organ systems can be directly or indirectly injured by bacterial toxins, circulating cytokines, and the products of activated white blood cells. The end result of these complex and interrelated pathologic mechanisms is MODS, which describes the serial and progressive failure of various organ systems and is associated with increased morbidity and mortality (see also Chapter 112).[15-17]

Pathogenesis

Introduction

Many clinical and basic science studies have focused on the mechanisms underlying the development of sepsis. At least three major hypotheses have been proposed to explain the development of sepsis and its sequelae. The first hypothesis attributes the development of sepsis to an excessive or uncontrolled host inflammatory response. This "proinflammatory" hypothesis is broadly consistent with the concept of SIRS and is generally well supported by experimental and clinical data. However, a large number of clinical trials aimed directly at inhibition of various components of this putative excessive inflammatory response have failed, thus leading to the development of alternative hypotheses. One such alternative hypothesis states that sepsis is not directly the result of excessive inflammation but rather a more direct manifestation of failed antiinflammatory responses. Thus, in this alternative hypothesis there is direct failure of the compensatory antiinflammatory response syndrome (CARS), which subsequently permits unchecked proinflammatory responses. Related to the CARS concept is the concept of immunoparalysis (see also Chapter 105), which embodies the third overall hypothesis to account for the clinical manifestations of sepsis. The hypothesis of immunoparalysis postulates that sepsis is not a manifestation of too much or too little inflammation but rather a form of acquired immunodeficiency (both innate and adaptive immunity), leading to an inability to effectively clear pathogens and their products, which thereby cause direct tissue and organ injury.[18,19]

A conceptual framework for integrating these three hypotheses/paradigms is provided in Fig. 111.1. All three paradigms are biologically plausible and supported by the existing literature.[20] While seemingly vastly different in concept, they are not mutually exclusive in the context of a highly heterogeneous syndrome such as human sepsis. It is plausible that all three paradigms are valid across a given cohort

of heterogeneous patients with sepsis. In addition, each paradigm has the potential to influence all of the other paradigms, as indicated in Fig. 111.1. The following sections review the existing literature supporting these three paradigms and will serve to frame the important concept of heterogeneity in sepsis. A major challenge in the field of sepsis is to more effectively understand how a given patient fits into one of these three paradigms (ie, stratify or phenotype patients more effectively).

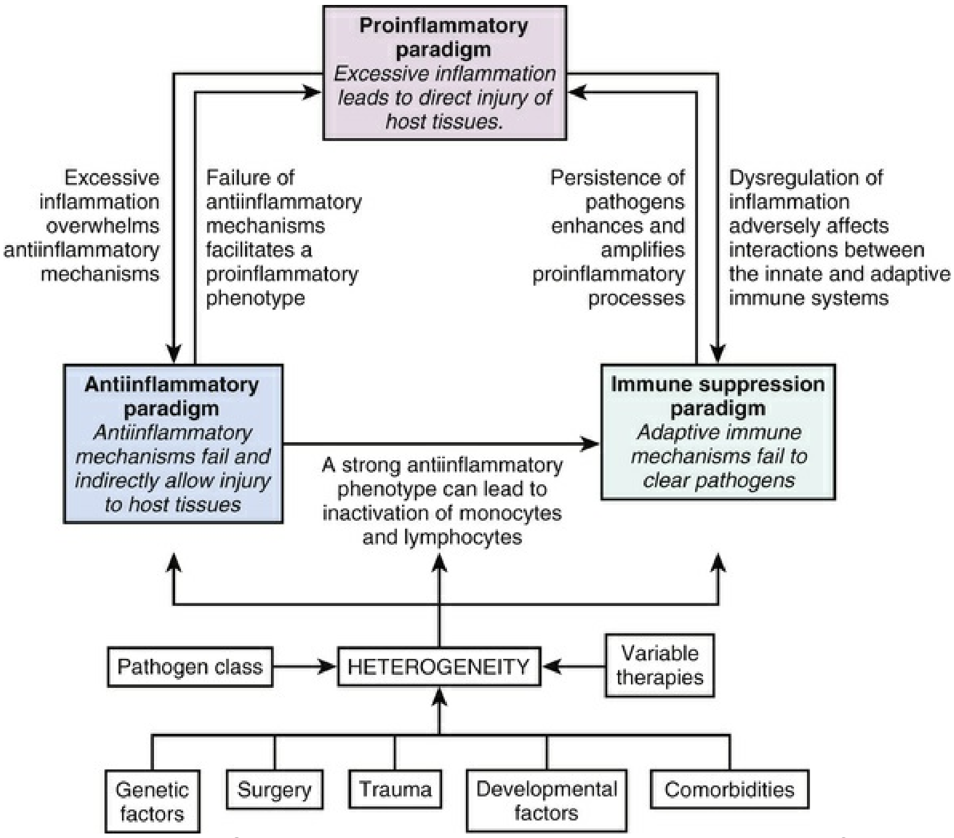

FIG. 111.1 Schematic depicting the three major paradigms for understanding the pathophysiology of sepsis and septic shock. Although these paradigms are mechanistically distinct, they are not mutually exclusive. Each paradigm has the potential to influence the other paradigms, and all are potentially operative in a heterogenous patient cohort. Heterogeneity is a major component of septic shock and results from multiple host and environmental factors.

Pathogen Recognition and Signal Transduction

The fundamental role of the immune system is to detect, contain, and eradicate invading pathogens. The first step in this process involves pathogen recognition, which is achieved by the activation of pattern recognition receptors (PRRs) on immune cells by pathogen-associated molecular patterns (PAMPs)[21] (see also Chapter 101). Examples of PAMPS include lipopolysaccharide from the cell wall of gram-negative bacteria; lipoteichoic acid from the cell wall of gram-positive bacteria; mannans from the cell wall of yeast; double-stranded RNA of viruses; and unmethylated, CpG-rich DNA unique to bacterial genomes. The most well-studied

PRRs include the family of Toll-like receptors (TLRs), which can have relatively specific recognition of PAMPS.[21] For example, TLR-4 recognizes lipopolysaccharide, whereas TLR-2 recognizes lipoteichoic acid. Other examples of PRRs or PRR components include CD-14, scavenger receptors, nucleotide-binding oligodimerization (NOD) receptors, pentraxins, and collectins.[22]

Engagement of PRRs on the cell surface of immune cells, by PAMPS, leads to activation of the immune system in the form of phagocytosis, proliferation, and production/secretion of cytokines. The latter process, cytokine expression, serves to orchestrate, direct, and amplify the innate and adaptive immune response toward pathogen eradication. However, if this process becomes dysregulated, this same production of cytokines, though required for pathogen eradication, can inadvertently lead to autoinjury of the host.

Much of the activation of the immune system on PRR activation relies on signal transduction mechanisms, which serve to transfer the signal of pathogen recognition at the cell surface to the intracellular compartment in order to induce new gene expression or a change in cellular function. One of the major signal transduction mechanisms of the immune system is the NF-κB pathway, which serves as a master "switch" for the expression of a wide variety of genes involved in inflammation and immunity. Indeed, activation of the NF-κB pathway is a major signaling pathway in the pathophysiology of sepsis and may represent a potential therapeutic target.[23,24] Another major signaling pathway for the regulation of genes involved in inflammation and immunity is the mitogen-activated protein kinase (MAPK) signaling pathway. The MAP kinases consist of three major families: p38 MAP kinase, extracellular-regulated protein kinase (ERK), and c-Jun N-terminal kinases (JNKs). These major kinase families are also referred to as stress-activated protein kinases (SAPKs). Similar to the NF-κB pathway, the MAP kinases are also regarded as potential therapeutic targets in the context of sepsis.[23,25,26] Finally, there is now increased attention on the phosphatase family of intracellular signaling molecules in the context of sepsis. Whereas kinases direct cellular signaling by adding phosphate groups to intracellular signaling proteins, phosphatases serve to remove phosphate groups from these same intracellular signaling proteins and can thus serve to modulate proinflammatory cell signaling.[27,28]

Cytokines as Principal Mediators of the Sepsis Response

Cytokines represent a broad family of proteins that have paracrine, autocrine, and endocrine properties, as well as the ability to regulate and modulate virtually all aspects of immunity and inflammation. Common features of cytokines are provided in Box 111.2. Following is a review of a selected group of cytokines thought to play an important role in the pathophysiology of sepsis.

Box 111.2

Common Features of Cytokines

- Cytokine secretion is relatively brief and self-limited.

- Secretion of many cytokines requires new mRNA transcription and new protein translation.
- Expression and secretion is regulated by specific cellular signals.
- A given cytokine can have multiple cellular sources.
- A given cytokine can have multiple cellular targets.
- A given cytokine can have multiple functions regarding cellular function or activation.
- Cytokines can have redundant activities/functions with other cytokines.
- Many cytokines regulate the activity and expression of other cytokines.

Tumor necrosis factor-α (TNF-α) is perhaps the most well-studied cytokine causally linked to sepsis. Evidence for TNF-α mediation of sepsis includes the observations that TNF is produced by hematopoietic cells, its expression is temporally related to the development of shock, it can by itself induce experimental septic shock in animals, and passive immunization against TNF blunts the endotoxin-induced sepsis response.[29] The proinflammatory effects of TNF include leukocyte-endothelial cell adhesion, transformation to a procoagulant phenotype, induction of inducible nitric oxide synthase, and functioning as a principal "early" cytokine inducing the subsequent cascade of mediators and cytokines promulgating the septic response. Despite a plethora of preclinical studies demonstrating the important proximal role of TNF-α in the pathophysiology of sepsis, multiple clinical trials targeted at neutralization of TNF-α activity have thus far failed to demonstrate efficacy.[30]

Interleukin-1beta (IL-1β) has many redundant biological properties to that of TNF-α and is also considered to be a major early cytokine in the sepsis response.[31] IL-1β leads to inflammatory and immune cell activation via the NF-κβ and MAPK pathways. Also, similar to TNF-α, clinical trials targeted at neutralization of IL-1β activity have thus far failed to demonstrate efficacy despite promising preclinical data.

IL-6 expression is highly dependent on TNF-α and IL-1β and is consistently found to be elevated during the course of sepsis.[32] IL-6 is a pleiotropic cytokine possessing a number of functions including driving the acute-phase response in hepatocytes, differentiating myeloid cells, stimulating immunoglobulin production, and activating T-cell proliferation.[33] Because increased IL-6 admission levels have been correlated with death in the context of sepsis, there has been interest in using IL-6 as a stratification biomarker for interventional clinical trials in sepsis. While this stratification approach has been highly effective in animal models of sepsis,[34] it has thus far failed when applied in the clinical setting.[35]

IL-8 is a canonical member of the chemokine subclass of cytokines.[36] The term "chemokine" refers to the ability of certain cytokines to serve as chemoattractants, which direct leukocyte movement to sites of infection and inflammation (chemotaxis). Both TNF-α and IL-1β can induce IL-8 production from a variety of cells, including endothelial cells, macrophages, neutrophils, and epithelial cells. IL-8

is the principal human chemoattractant for neutrophils and appears to play a major role in the recruitment of neutrophils to the lungs in patients with sepsis-induced ARDS.[37] Serum IL-8 measurements within 24 hours of presentation to the ICU can robustly predict good outcome in children with septic shock receiving standard care.[38] Other chemokines relevant to the pathophysiology of septic shock include monocyte chemoattractant protein 1 (MCP-1) and macrophage inflammatory protein-1 (MIP-1).[36]

Macrophage migration inhibitory factor (MIF) is another important cytokine in the pathophysiology of sepsis, and high levels of MIF in patients with septic shock and ARDS correlate with poor outcome.[39,40] MIF possesses a number of biological activities generally directed toward a proinflammatory phenotype, including skewing of naïve T cells toward a Th1 phenotype. An unusual feature of MIF is that its secretion is enhanced by glucocorticoids, whereas the expression and activity of many cytokines are suppressed by glucocorticoids. In turn, MIF has the ability to antagonize the antiinflammatory effects of glucocorticoids.

Intereleukin 18 (IL-18) has also emerged as an important cytokine in the pathophysiology of sepsis.[41] Depending on the local cytokine milieu, IL-18 has the ability to skew naïve T cells toward either a Th1 or Th2 phenotype. In addition, it appears IL-18 may serve as an early biomarker to distinguish between gram-positive and gram-negative sepsis. IL-10 is the best studied and most well-known antiinflammatory cytokine.[42,43] As an antiinflammatory cytokine, IL-10 serves to antagonize the proinflammatory effects of other cytokines and can thereby keep inflammation "in check." IL-10 inhibits expression of cytokines such as TNF-α, IL-1β, and IL-8 and can inhibit expression of adhesion molecules. In addition, IL-10 can "deactivate" monocytes by downregulating the expression of MHC surface molecules. Thus IL-10 has a number of interesting properties that could potentially be leveraged therapeutically to limit excessive inflammation during sepsis. This theoretic consideration must be tempered by the ability of IL-10 to deactivate monocytes and thereby potentially impair the ability to adequately clear infection (ie, the immune suppression paradigm depicted in Fig. 111.1). Indeed, it has been reported that in children with MODS, higher plasma IL-10 levels correlate with higher mortality and higher monocyte mRNA levels of IL-10 correlate with increased length of stay in the ICU.[44] Similar observations have been reported in adult patients with septic shock.[45]

High-mobility group box 1 (HMGB-1) has long been known as a nonhistone DNA binding protein. More recently, it has been recognized that HMGB-1 also exists in the extracellular compartment, appears to have proinflammatory properties that may play a role in the pathophysiology of sepsis, and may represent a potential therapeutic target for sepsis.[46] The attraction of HMGB-1 as a therapeutic target in sepsis stems from the observation it may be a "late mediator" of sepsis inasmuch as it appears in the extracellular compartment within a time frame that is considerably later than that seen with the canonical sepsis cytokines such as TNF-α and IL-1β. Thus the kinetics of HMGB-1 expression provide a potential therapeutic window that may be clinically feasible to exploit. This temporal observation is evident in both experimental models of sepsis and in humans with established septic shock.[47] The biological properties of HMGB-1 appear to involve activation of Toll-like receptors and the receptor for advanced glycation end products (RAGE). More recently, it has been suggested HMGB-1 intrinsically possesses little proinflammatory biological

activity but forms highly proinflammatory complexes with cytokines (eg, IL-1β) and PAMPS (eg, bacterial DNA and lipopolysaccharide).[48]

HMGB-1 is also a prime example of a class of molecules known as “alarmins” or danger/damage-associated molecular patterns (DAMPs).[49] Broadly speaking, DAMPs represent a class of molecules normally existing in the intracellular compartment at baseline but are released from damaged cells into the extracellular compartment during conditions such as trauma or sepsis. DAMPs appear to signal through many of the same PRRs recognizing pathogens and therefore have the ability to activate the immune/inflammatory system. Because DAMPs are released from damaged cells, they can serve to “alert” the inflammatory system of systemic “damage” or “danger” and can therefore induce appropriate and adaptive activation of defense mechanisms. Alternatively, excessive DAMP-mediated activation of PRRs can lead to unnecessary and maladaptive amplification of inflammation damaging to host tissues. Other examples of DAMPs include calgranulins, hepatoma-derived growth factor, heat shock proteins, and uric acid. In this regard, heat shock proteins have been reported to be substantially elevated in the serum of children with septic shock.[50,51] More recently, formyl peptides released from mitochondria and mitochondrial DNA were reported as novel DAMPs.[52]

Adhesion Molecules

An important breakthrough in the molecular understanding of sepsis-induced organ dysfunction came with the identification of the processes responsible for the infiltration of leukocytes into tissues.[53] The “leukocyte-endothelial cell adhesion cascade” (Fig. 111.2) is characterized by early cytokine-mediated activation of the selectin family of endothelial cell adhesion molecules that can mediate a process of neutrophil “rolling” whereby sialyated moieties constitutively present on neutrophils interact with selectins on the endothelial cell membrane (eg, E-selectin). In the second phase, activation of the “rolling” neutrophil causes increased expression and activation of the integrin family of adhesion molecules that interact with the similarly upregulated intercellular adhesion molecule (ICAM)-1 on the endothelial cell surface. This ligand interaction facilitates firm adhesion of the neutrophil to the endothelium. Subsequently, in response to a variety of chemotactic molecules, neutrophils transmigrate through the endothelial junctions to the site of inflammation. Release of a variety of radical species, both oxygen and nitrogen based, and proteases by the activated neutrophils can contribute to pathogen eradication, but paradoxically they can also cause endothelial and tissue injury.

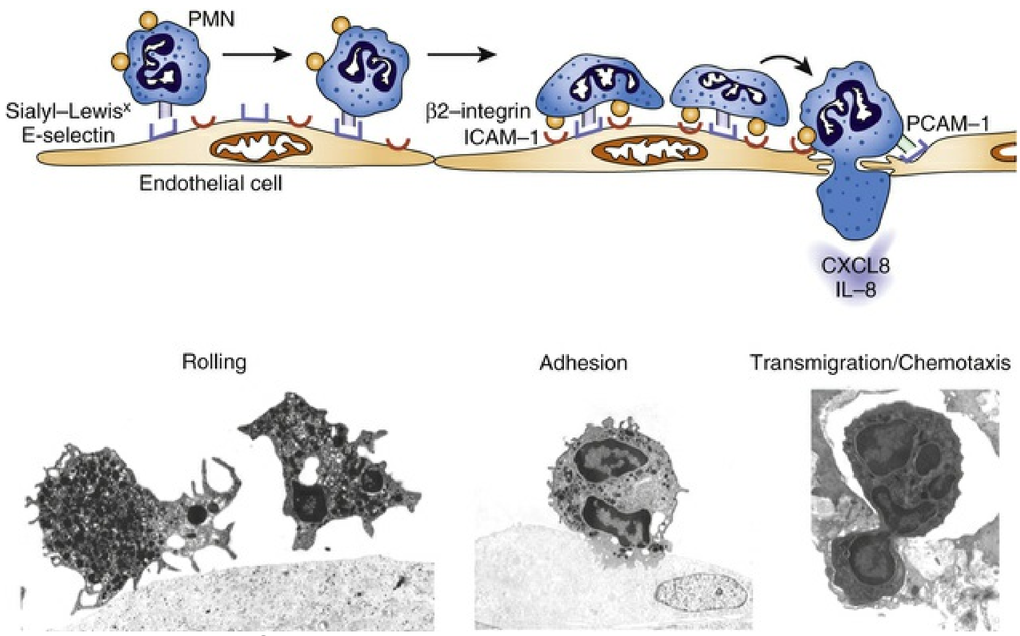

FIG. 111.2 Schematic and corresponding electron micrographs highlighting the process of leukocyte-endothelial cell adhesion and leukocyte transmigration from the intravascular compartment to the extravascular compartment. Cytokine-mediated activation of the selectin family of endothelial cell adhesion molecules mediate neutrophil "rolling" followed by ICAM-1-mediated adhesion. After adhesion, neutrophils transmigrate across "openings" between enothelial cell junctions to enter the extravascular space. The transmigration process is directed by chemokines serving as homing signals for neutrophils and other leukocytes. (Courtesy Thomas P. Shanley, MD, University of Michigan.)

Nitric Oxide

Nitric oxide (NO) was discovered in the 1980s as the molecule responsible for endothelial-derived relaxation of blood vessels.[54,55] Since then, NO has received tremendous attention as a potential mediator of septic shock.[56] NO is produced by the enzyme, nitric oxide synthase (NOS), which converts arginine and oxygen to NO and citrulline. Human NOS exists as three different isoforms (NOS 1, 2, and 3), and each isoform has relatively unique tissue localizations, requirements for NO production, and kinetics of NO production. Several features of NO-related biology support an important role in the pathophysiology of sepsis. First, NOS2 (a.k.a. inducible NOS) is expressed in response to proinflammatory signals (eg, lipopolysaccharide, TNF-α, and IL-1β) and produces large amounts of NO for prolonged periods of time. Second, NO can induce pathologic vasodilation and function as a myocardial depressant. Third, NO can function as an oxidant either alone or by contributing to formation of other highly oxidizing, reactive molecules such as peroxynitrite. Fourth, NO has the potential to negatively affect mitochondrial function. Finally, elevated levels of NO metabolites have been well documented in children with septic shock and the levels correlate with the degree of cardiovascular dysfunction.[57,58] Despite these intriguing biological properties and a wealth of preclinical data testing the efficacy of NOS inhibition, clinical trials targeted at NOS inhibition have failed to demonstrate efficacy.[59] Because NO has a

myriad of biological properties important for homeostasis (particularly when NO is produced by the NOS1 and NOS3 isoforms), this lack of efficacy may represent the timing and specificity of NOS isoform inhibition.

Coagulation Cascade

It is now well established that the inflammatory cascade is directly linked to the coagulation cascade, and the coagulation cascade can be pathologically activated in the context of sepsis.[60,61] This pathologic activation leads to disseminated intravascular coagulation, which subsequently leads to endothelial cell dysfunction and microvascular thrombosis. If the endothelial dysfunction and microvascular thrombosis progress to a critical threshold, end-organ failure ensues.

A complex network of multiple mediators takes part in this pathologic process including proinflammatory cytokines, tissue factor, antithrombin III, protein C, protein S, tissue factor pathway inhibitor, and plaminogen activator inhibitor type 1 (PAI-1). Increased PAI-1 levels are a particularly strong feature of severe cases of meningococcemia and may be causally linked to a polymorphism in the promoter region of the *PAI-1* gene.[62,63] Depressed levels of the endogenous anticoagulants, antithrombin III, protein S, and protein C are consistently documented in the context of septic shock. These observations have led to multiple clinical trials in which recombinant forms of these endogenous anticoagulants have been administered to patients with septic shock. The majority of these trials did not demonstrate efficacy. Studies in the early 2000s suggested recombinant activated protein C (APC) reduced mortality in adult patients with septic shock, and this compound subsequently received FDA approval.[61] The beneficial effects of APC in septic shock are thought to be secondary to both prevention of microvascular thrombosis and an antiinflammatory effect.[64] Unfortunately, a phase III trial of APC therapy in children with septic shock, the RESOLVE trial, failed to demonstrate efficacy.[65] The RESOLVE trial was terminated after the second interim analysis due to little chance of reaching the primary efficacy end point. In addition, there was an increased risk of serious bleeding events in patients younger than 2 months of age. Consistent with this finding in children, a subsquent trial in adults with septic shocks, PROWESS-SHOCK, also failed to confirm earlier findings of improved mortality, and activated protein C was removed from the market in 2011.[66] Nonetheless, the RESOLVE trial represents the largest and most well-organized pediatric septic shock trial to date and provides an important context and reference point for all future interventional trials in the field of pediatric critical care medicine.

Related to the paradigm of altered coagulation playing an important role in the pathophysiology of sepsis is the concept of thrombocytopenia-associated multiple organ failure (TAMOF).[67] New-onset thrombocytopenia in critically ill patients correlates with the evolution of persistent organ failure and poor outcome, including patients with sepsis. The mechanistic link between thrombocytopenia and organ failure is thought to involve a form of microangiopathy analagous to thrombotic thrombocytopenic purpura, including substantial decreases of ADAMTS-13 (A Disintegrin And Metalloprotease with ThromboSpondin motifs). ADAMTS-13 regulates microvascular thrombosis by cleaving the large thrombogenic von Willebrand factor multimers into smaller, less thrombogenic forms. Preliminary experience indicates plasma exchange restores ADAMTS-13 levels and restores

organ function in children with TAMOF.[68] At the time of this writing, clinicians and researchers await the results of an observational, prospective cohort study further evaluating the efficacy of plasma exchange in patients with TAMOF (NCT00118664). Ultimately, the efficacy of plasma exchange for TAMOF will require more definitive evidence by way of a formal randomized trial.

Peroxisome Proliferator-Activated Receptor-γ (PPARγ) Pathway

PPARγ is a member of the PPAR nuclear receptor superfamily and a ligand-activated transcription factor having well-known effects on lipid metabolism and cell proliferation.[69] The thiazolidinedione class of insulin-sensitizing drugs are well-known PPARγ ligands (activators) and are currently widely used in the management of type II diabetes. Recently, it has become evident that pharmacologic activation of PPARγ has important antiinflammatory effects of significant benefit in experimental models of critical illness, including sepsis.[70-75] The recent demonstration that PPARγ expression and activation are indeed altered in children with septic shock, coupled with the availability of FDA-approved PPARγ ligands, provides an opportunity to test the efficacy of PPARγ ligands in sepsis.[76] There is currently an active Phase 1 study to evaluate the pharmacokinetics and safety of the PPARγ ligand, pioglitazone, in children with sepsis (NCT01352182).

Myeloid-Derived Suppressor Cells (MDSC)

The neutrophil is often considered the first line in the innate immune response to infection. Patients with sepsis can present with elevated or extremely low neutrophil counts. In either case the physiologic response to infectious stimuli is "emergency granulopoiesis" to generate a large number of myeloid cells to deal with the onslaught of infectious particles. This can lead to a much-needed increase in cells to both contain and eliminate pathogens; however, in patients with sepsis this can also give rise to a recently described MDSC population.[77] These cells produce antiinflammatory cytokines and suppress T-cell activation and thus may contribute in part to the failure of the adaptive immune system.[78] These cells have been primarily characterized in the mouse model of sepsis, where up to 30% of cells in the spleen 10 days after sepsis are MDSCs.[79] Whether these cells are helpful to the immune response or lead to further immune suppression is not entirely clear.[79,80] MDSCs can also be found in patients with other inflammatory conditions such as cancer and autoimmunity.[77] Further research is necessary to determine if MDSCs represent a physiologically orchestrated part of the immune response or a pathologic arrest of developing myeloid cells leading to immune suppression.

Paradigm of Sepsis as an Adaptive Immune Problem

The conceptual framework of the pathophysiology of sepsis has evolved to include the concept of immune paralysis. Whereas sepsis has been traditionally viewed as being a reflection of uncontrolled hyperinflammation (ie, an innate immunity problem), it is now thought sepsis also has a strong, perhaps predominant, "antiinflammatory" component manifested as immune suppression and the relative

inability to effectively clear an infectious challenge (an adaptive immunity problem).[18,19,81,82] For example, monocyte deactivation related to decreased MHC gene mRNA expression and decreased surface expression of MHC molecules have been previously demonstrated in patients with septic shock, including children.[44,45,83,84] With regard to lymphocyte dysfunction, Heidecke et al.[85] demonstrated that adult patients with intraabdominal infections and septic shock have defective T-cell proliferation and defective T-cell–dependent cytokine secretion, all of which are consistent with anergy/immune suppression. Felmet and et al.[86] identified prolonged lymphopenia and apoptosis-associated depletion of lymphoid organs as independent risk factors for the development of nosocomial infections and multiple organ failure in critically ill children. Musyznski et al.[87] recently provided evidence for early adaptive immune dysfunction in children with septic shock, as measured by ex vivo production of interferon-γ by CD4 cells.

Animal studies have well documented the requirement of an intact T-cell system to adequately combat a septic challenge.[82,88] Interestingly, however, neonatal mice (4-6 days of age) do not require an intact adaptive immune system to clear infection.[89] More recently, animal-based experiments have demonstrated that experimental septic shock is characterized by widespread apoptosis of T cells, and preventing T-cell apoptosis positively impacts the outcome of experimental sepsis.[90-97] Importantly, the concept of T-cell apoptosis in human sepsis has been indirectly corroborated by autopsy studies, including children,[86,98] and lymphocyte-based immunophenotyping was recently demonstrated to effectively stratify septic shock outcome in adults.[99] Finally, it has been recently demonstrated in experimental models that alterations of the adaptive immune system in sepsis can persist well beyond the acute period (up to at least 6 weeks) via epigenetic mechanisms involving dendritic cells.[100,101] Despite these data, formal studies of T-cell function and adaptive immunity in pediatric septic shock have never been conducted in a systematic and comprehensive manner. Such studies hold the promise of radically changing our conceptual approach to the long-sought, but not yet realized, goal of rational immune modulation in septic shock (see also Chapter 102).

Genomic Medicine and Sepsis

The initial elucidation and publication of the human genome, the development of molecular biology tools for efficient high-throughput data generation, and the evolution of the field of biomedical informatics have combined to generate a new field termed “genomic medicine” and the related field of “systems biology.” All aspects of medicine are potentially amenable to the concepts of genomic medicine and systems biology, including pediatric sepsis. One skeptical perspective of this concept is that clinical pediatric sepsis is overly heterogeneous and multifactorial to be credibly interrogated by the current genomic and systems biology approaches. An alternative and more optimistic perspective is that the concepts of genomic medicine and systems biology are ideally suited to more effectively address the complex syndromes clinicians encounter in pediatric critical care medicine, such as septic shock. The authors now address the two areas of genomic medicine most well developed in the field of pediatric septic shock: candidate gene association studies and genome-wide expression profiling.

Genetic Influence and Septic Shock

Susceptibility to sepsis and the clinical course of patients with sepsis are both highly heterogeneous, thus raising the strong possibility that the host response to infection is, at least in part, influenced by heritable factors (ie, genetics).[102] A landmark study by Sorensen et al.,[103] published more than 25 years ago, provides strong evidence linking genetics and susceptibility to infection. This study involved a longitudinal cohort of more than 900 adopted children born between 1924 and 1926. The adopted children and both their biological and adoptive parents were followed through 1982. If a biological parent died of infection before the age of 50 years, the relative risk of death from infectious causes in the child was 5.8 (95% CI 2.5–13.7), which was higher than for all other causes studied, including cancer and cardiovascular/cerebrovascular disease. In contrast, the death of an adoptive parent from infectious causes did not confer a greater relative risk of death in the adopted child.

More recently, investigations attempting to link genetics with sepsis focused mainly on candidate gene association studies and gene polymorphisms. A gene polymorphism is defined as the regular occurrence (>1%) in a population of two or more alleles at a particular chromosome location. The most frequent type of polymorphism is called a single nucleotide polymorphism (SNP): a substitution, deletion, or insertion of a single nucleotide occurring in approximately 1 per every 1000 base pairs of human DNA. SNPs can result in an absolute deficiency in protein, an altered protein, a change in the level of normal protein expression, or no discernible change in protein function or expression. There is a growing body of literature linking SNPs within several genes regulating inflammation, coagulation, and the immune response with critical illness, and several excellent reviews exist on the topic.[104-107]

The signaling mechanisms involved in pathogen recognition, the immune response, and inflammation were described in previous sections. Following is an overview of relevant SNPs described in many of the genes involved in these signaling mechanisms. TLR-4 (the primary receptor for recognition of lipopolysaccharide) mutations have been described in humans, all of which increase susceptibility to infections secondary to gram-negative organisms.[108] While several SNPs in the *TLR-4* receptor gene have been described, few have been found to be associated with an increased risk of septic shock or septic shock–related mortality in children. For example, an adenine for guanine substitution 896 base pairs downstream of the transcription start site for TLR-4 (+896) results in replacement of aspartic acid with glycine at amino acid 299 (Asp299Gly). The Asp299Gly polymorphism has been associated with reduced expression and function of the TLR-4 receptor in vitro.[108,109] Furthermore, adults who carry the Asp299Gly polymorphism appear to be at increased risk for septic shock and poor outcome in several cohort studies.[110-112] While children who carry the Asp299Gly polymorphism appear to be at increased risk of urinary tract infection, this SNP does not appear to influence either the susceptibility or severity of meningococcal septic shock in children.[113,114] These results were further corroborated in a cohort study involving over 500 Gambian children.[115]

SNPs related to other members of the LPS-receptor complex (eg, CD14, MD-2, and MyD88) have been studied in adult populations, but no such studies have yet to be

performed in children.[111,116-119] SNPs in other classes of Toll-like receptors have also been studied. For example, gene polymorphisms of TLR-2, the primary pattern recognition receptor for gram-positive bacteria, have been associated with increased risk of infection in children and adults.[120-122]

Several SNPs affecting cytokine expression have been described, but the corresponding gene association studies in critically ill adults with septic shock have been conflicting.[106,107,123] For example, two allelic variants of the TNF-α gene have been described: the wild-type allele TNF1 (guanine at -308A) and TNF2 (adenosine at -308A). The TNF2 allele has been associated with higher expression of TNF-α and increased susceptibility to septic shock and mortality in at least one study involving critically ill adults.[124] Nadel et al.[125] found an increased risk of death in critically ill children with meningococcal septic shock who carried the TNF2 allelic variant. Several additional SNPs in TNF-β, IL-1, IL-6, IL-8, and IL-10 have also been shown to influence susceptibility to and severity of septic shock in children.[126-132]

Because dysregulation of the coagulation cascade plays an important role in the pathophysiology of septic shock, several studies have examined polymorphisms of key genes involved in coagulation. For example, the 4G allele of a deletion/insertion (4G/5G) SNP in the promoter region of the plasminogen-activator inhibitor type-1 *(PAI-1)* gene has been associated with higher plasma concentrations of PAI-1. The 4G allele increases susceptibility to and severity of septic shock, as well as increasing the risk of mortality in children with meningococcal septic shock.[62,133-135] In addition, an SNP in the protein C promoter region has been associated with susceptibility to meningococcemia and illness severity in children.[136]

SNPs in genes involved in phagocytosis and the complement cascade have also been studied in the context of septic shock. For example, SNPs affecting function have been described in virtually all family members of the Fcγ receptor (important for phagocytosis), and several of these SNPs have been associated with susceptibility to meningococcal sepsis, severity of meningococcemia, and poor outcome from meningococcal septic shock.[137-143] In addition, an association between the FcγRIIa polymorphism and infection with other encapsulated bacteria has also been reported.[144,145] Several SNPs in the mannose-binding lectin (MBL) gene have been associated with increased susceptibility to infection, as well as increased illness severity.[146-151] Finally, an SNP of the bactericidal permeability increasing protein (BPI) gene has also been associated with increased mortality from septic shock in children.[152] This polymorphism is particularly interesting because a well-conducted phase III trial of recombinant BPI in children with septic shock failed to demonstrate efficacy.[153]

It is likely that many more studies that attempt to link SNPs with the susceptibility and/or outcome of pediatric septic shock are forthcoming in the future, and all need to be carefully considered and evaluated. With respect to validity and wide clinical acceptance, the ideal candidate gene association study requires several important qualities including biological plausibility, large sample sizes, a priori hypothesis statements, and power calculations, accounting for confounding factors, and independent validation.[154]

Genome-Wide Expression Profiling in Children With Septic Shock

The development of microarray technology has provided an unprecedented opportunity to efficiently measure genome-wide mRNA expression patterns in clinical samples. Over the past decade, this approach has been leveraged to understand more comprehensively the pathophysiology of pediatric septic shock and as a means of discovery and hypothesis generation. Comprehensive reviews of these studies were recently published.[155-157]

The first studies to characterize the transcriptomic response of pediatric septic shock confirmed that septic shock is characterized by upregulation of gene programs corresponding to innate immunity and the inflammatory response.[158,159] These studies also noted concomitant downregulation of gene programs corresponding to adaptive immunity, which is consistent with the immune paralysis paradigm described earlier. These gene expression patterns are evident within 24 hours of admission to the ICU and persist at least through ICU day 3.[160] Other notable data generated from these transcriptomic studies include (1) the observation that pediatric septic shock is characterized by repression of gene programs that either depend on zinc homeostasis or directly participate in zinc homeostasis[158]; (2) characterizing distinct gene programs across the spectrum of systemic inflammatory response syndrome, sepsis, and septic shock[161]; (3) demonstrating the influence of developmental age on the transcriptomic response to pediatric septic shock[162]; (4) the observation that gene programs corresponding to mitochondrial function and biogenesis are repressed in certain subclasses of pediatric septic shock[163]; and (5) the observation that the prescription of adjunctive corticosteroids leads to further repression of adaptive immunity-related gene programs in children with septic shock.[164]

These transcriptomic studies have also enabled identification of new mechanistic pathways and candidate therapeutic targets for sepsis, which have been brought back to the basic science laboratory for formal hypothesis testing using rodent models of sepsis. For example, following the observation that zinc homeostasis is altered in pediatric septic shock, it was demonstrated that zinc supplementation confers a survival advantage in rodent models of sepsis.[75,165] As a direct consequence, a phase 1 trial of IV zinc supplementation in critically ill children was recently completed and will inform the design of future trials of zinc supplementation in sepsis.[166] In another example, it was reported that repression of the peroxisome proliferator activator receptor-α (PPAR-α) signaling pathway is associated with poor outcome in pediatric sepsis.[167-169] This observation was subsequently corroborated in a sepsis model involving PPAR-α null mice.[170]

Following the observation that matrix metalloproteinase-8 (MMP8) is consistently the highest expressed gene in children with septic shock, extensive studies were subsequently conducted to further delineate the role of MMP8 in sepsis. Genetic ablation or pharmacologic inhibition of MMP8 confers a survival advantage in mice subjected to cecal ligation and puncture (CLP).[171,172] These observations are associated with attenuated inflammation but without compromising bacterial clearance. In addition, MMP8 can directly serve as a DAMP because primary macrophages stimulated ex vivo with recombinant MMP8 demonstrate increased NF-κB expression and increased expression of proinflammatory cytokines.[171]

These transcriptomic studies have also enabled the discovery of sepsis biomarkers. For example, IL-27 was identified as a candidate sepsis diagnostic biomarker via transcriptomics and follow-up studies demonstrated serum IL-27 protein

concentrations >5 ng/mL can distinguish critically ill children with bacterial infection from critically ill children with sterile inflammation with >90% specificity and positive predictive value.[173] In these initial studies, IL-27 outperformed procalcitionin, and a combination of procalcitonin and IL-27 performed better than either biomarker alone. Interestingly, IL-27 appears to perform better as a sepsis diagnostic biomarker in children, compared with adults.[174,175] In another example, these transcriptomic studies enabled the discovery of biomarkers to predict the development of septic acute kidney injury.[176,177] Finally, these transcriptomic studies enabled the discovery of stratification biomarkers to assign a baseline mortality probability for children and adults with septic shock.[178-183] The concept of leveraging stratification biomarkers for the care of children with septic shock is discussed in a subsequent section.

An "endotype" is a subclass of a condition defined by function or biology.[184] On the basis of discovery-oriented computational approaches and hierarchical clustering of >8000 genes, these transcriptomic studies identified gene expression–based endotypes of pediatric septic shock.[167] Post hoc analysis revealed one of the endotypes had significantly greater illness severity, organ failure burden, and mortality, and these observations were subsequently validated.[168,169] With the goal of developing a clinically feasible test meeting the time-sensitive demands of critically ill patients,[155] the endotyping method was refined by distilling the endotype-defining expression signature to the top 100 class predictor genes, expressing these genes using visually intuitive gene expression mosaics, and measuring mRNA expression using a digital mRNA quantification platform. This approach validated that this endotyping method identifies patients with increased organ failure burden and mortality.[185,186] Notably, the endotype-defining gene expression signature is enriched for genes corresponding to adaptive immune function and the glucocorticoid receptor signaling pathway, and allocation to one of these endotypes is independently associated with increased mortality. Thus endotyping potentially has theranostic implications given the current interest surrounding therapies to augment the adaptive immune system in patients with sepsis[187] and the ongoing controversies surrounding the role of adjunctive corticosteroids in septic shock.[188] For example, the use of adjunctive corticosteroids is independently associated with four times the risk of mortality in one of the endotypes.[185] Fig. 111.3 shows examples of the recently identified pediatric septic shock endotypes.

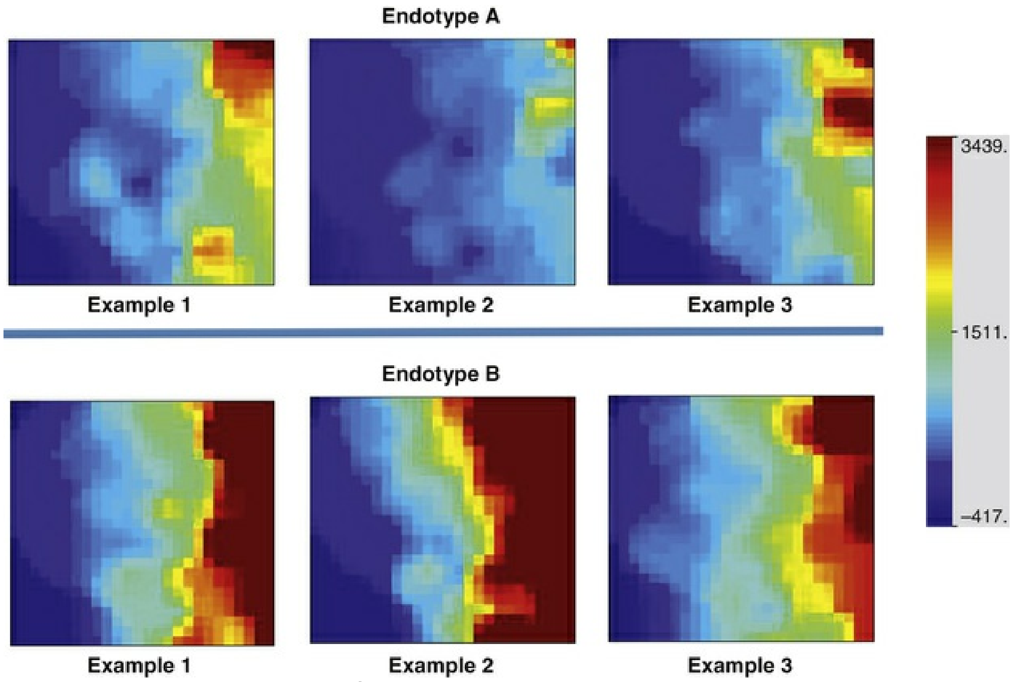

FIG. 111.3 Examples of individual pediatric patients allocated to septic shock endotypes A and B. Each gene expression mosaic represents 100 endotype-defining genes, which correspond to adaptive immunity and glucorticoid receptor signaling.[185] The color bar on the far right of the figure indicates color intensity relative to the level of gene expression, with the degree of blue intensity corresponding to decreased gene expression and the degree of red intensity corresponding to increased gene expression.

Treatment Strategies

Overview

As the biological response to sepsis becomes better understood and as clinicians refine their ability to phenotype and stratify patients, the approach to treatment of sepsis will become more specific and more sophisticated. At present, however, clinical treatment of sepsis entails four important goals, which for the most part rely on purely supportive measures founded on the fundamental principles of critical care medicine: initial resuscitation, pathogen elimination, maintenance of oxygen delivery, and carefully directed regulation of the inflammatory response. An update of pediatric and neonatal specific guidelines for sepsis management was recently published,[189] and another update is in process at the time of this writing.

Initial Resuscitation

As in any disease process, the first step in the treatment of sepsis is the initial stabilization of the patient. In this regard, children present many of the same challenges as adult patients, including respiratory and cardiovascular stabilization. The primary goals of therapy in the first hours are to maintain oxygenation and ventilation, achieve normal perfusion and blood pressure, and reestablish appropriate urine output and mental status.[189]

Children with signs of sepsis may have significantly decreased mental status, raising concern about the ability to protect their airway. Also, in septic shock the work of breathing can represent a significant portion of oxygen consumption (as much as 15%-30%). Because children with septic shock also receive large amounts of fluid to restore intravascular volume in the context of capillary leak, they are at increased risk for developing pulmonary edema. Consequently, lung compliance decreases and work of breathing can increase substantially. Together, these respiratory abnormalities often necessitate tracheal intubation and mechanical ventilation. Arterial blood gas analysis often reveals, in early sepsis, respiratory alkalosis from centrally mediated hyperventilation. As sepsis progresses, patients may have hypoxemia and respiratory acidosis, secondary to parenchymal lung disease and/or hypoventilation due to altered mental status.[189] However, the decision to initiate mechanical ventilation support should not necessarily be contingent on laboratory findings; rather, the decision should be based primarily on clinical findings of increased work of breathing, hypoventilation, and/or impaired mental status. Mechanical ventilation provides the added benefit of reducing work of breathing, therefore decreasing overall oxygen consumption, especially when combined with sedation and paralysis. If early tracheal intubation is chosen, consideration of volume loading and inotropic/vasoactive support is recommended. Sedative agents for induction should be selected to maintain hemodynamic stability. The 2007 pediatric guidelines for septic shock specifically recommend against the use of etomidate due to its adrenal suppressive effects and suggest the use of ketamine as a suitable agent to maintain hemodynamic stability.[189] Subsequent studies, however, suggest no effect on mortality or length of stay in adults with septic shock intubated with etomidate.[190,191]

For a variety of reasons, patients with sepsis almost universally have decreased effective intravascular volume. Many had poor oral intake of fluid for some time before developing sepsis. With the development of increased vascular permeability, intravascular volume has been lost because of third spacing. Finally, vasodilation partially related to excessive NO production (see earlier section) results in abnormally increased vascular capacitance, thereby decreasing the effective intravascular volume. When sepsis is suspected, vascular access should be obtained and 20 mL/kg of isotonic fluid administered as quickly as possible. A second peripheral vascular access is recommended, and difficulties in attaining venous access can be overcome with the use of an intraosseous catheter. Intraosseous access can temporarily be the primary route for volume infusion, medications, and blood products when an intravascular access is not readily obtained. While following clinical examination for signs of overly aggressive volume resuscitation (eg, new onset of rales, increased work of breathing, development of a gallop, abdominal distention, or hepatomegaly), fluid should be administered quickly with the goal of improving blood pressure and tissue perfusion. Administration of more than 60 mL/kg of isotonic fluid in the first hour of resuscitation is associated with improved survival.[192-194]

Aggressive fluid resuscitation for septic shock was recently criticized as being only weakly supported by evidence.[195] Further, recent cohort studies have reported an association between positive fluid balance and increased mortality in adult and pediatric patients with sepsis, as well as other critical illnesses.[196-205] Most recently, the Fluid Expansion as Supportive Therapy (FEAST) study compared fluid boluses

of 20 to 40 mL/kg with no bolus in more than 3000 acutely ill African children and reported significantly increased mortality in the group randomized to the fluid bolus arm.[206] The FEAST study raises many questions regarding the efficacy of fluid resuscitation, even though the relevance for resource-rich environments is unclear.[207]

It is biologically and physiologically plausible that the association between a positive fluid balance and the risk of mortality is a result of confounding by illness severity. Positive fluid balance could be simply a marker of increased illness severity leading to increased vascular leak, increased third spacing of fluid, and increased fluid requirements, rather than a direct cause of increased mortality per se.[208] Accordingly, associations between positive fluid balance and septic shock outcomes need to be interpreted in the context of baseline mortality probability and illness severity. A recent study conducted a risk-stratified analysis of children with septic shock and found no association between the degree and duration of positive fluid balance and mortality in patients with intermediate and high baseline mortality risks.[209] At the time of this writing there is an ongoing study testing the efficacy of a "fluid sparing" protocol in children with septic shock (NCT1973907). It is hoped this study will further inform the issue of appropriate fluid resuscitation in pediatric septic shock.

Fig. 111.4 shows a pediatric algorithm for early goal-directed therapy. The algorithm emphasizes the importance of guiding therapy based on central venous oxygen saturation measurements. This algorithm reflects earlier studies in adults and children demonstrating reductions in sepsis-related mortality with goal-directed therapy guided by central venous oxygen saturation measurements.[210,211] However, the generalizability of the single pediatric study that led to this algorithm is questionable because of the high mortality in the control group. Similarly, a more recent study in children testing the efficacy of central venous oxygen saturation monitoring had an in-hospital mortality of 54% in the control group.[212] More importantly, three large adult trials were recently completed showing no benefit of goal-directed therapy, compared with standard care.[213-215] An important caveat of these three trials is that "standard care" has evolved considerably over the past decade to emphasize early recognition and early aggressive resuscitation of sepsis. A recent editorial opined that despite the results of the large adult studies, mixed venous saturation monitoring should remain a cornerstone target of guideline therapies for pediatric septic shock.[216] An alternative opinion is that the cumulative data support early recognition of sepsis and a highly attentive critical care team focused on early, aggressive resuscitation of septic shock, rather than supporting mixed venous oxygen saturations as a singular end point. Accordingly, an updated pediatric septic shock algorithm should de-emphasize the importance of central venous oxygen saturation per se and focus more generically on early recognition, attentiveness, and early aggressive resuscitation.

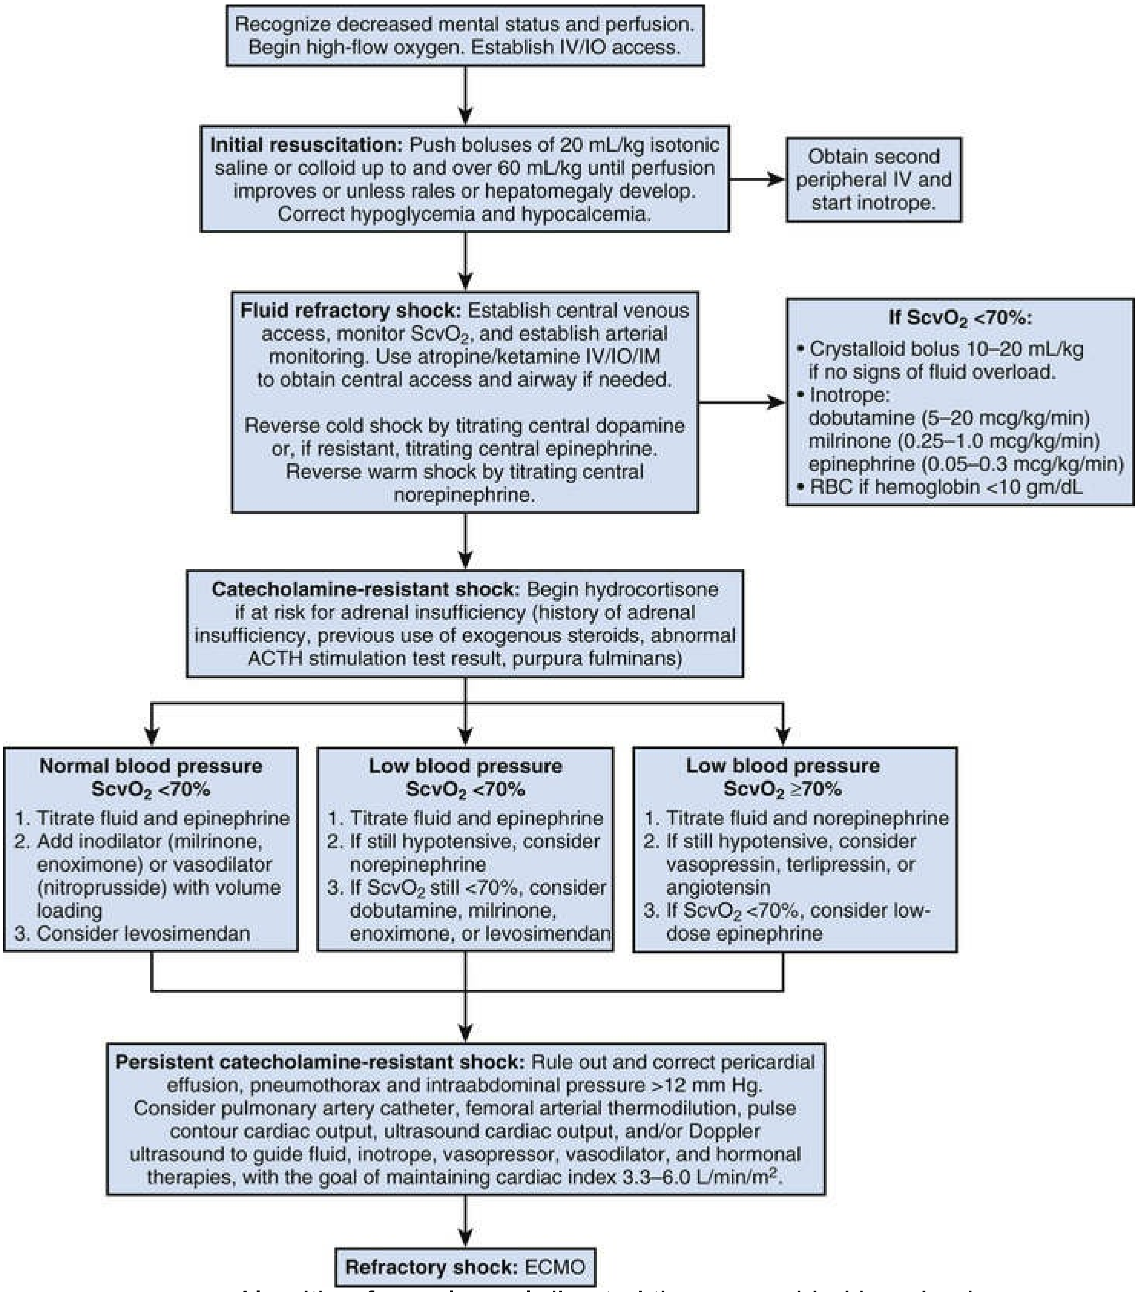

FIG. 111.4 Algorithm for early goal-directed therapy, guided by mixed venous saturations, in pediatric septic shock.

Cardiovascular agents are indicated for fluid refractory septic shock, and specific agent selection should ideally be predicated on the cardiovascular state of the patient. Patients with septic shock can present with low cardiac output and elevated systemic vascular resistance, high cardiac output and low systemic vascular resistance, or low cardiac output and low systemic vascular resistance. The incidence of sepsis-induced cardiac dysfunction in children is thought to be considerably higher than in adults, potentially representing up to 80% of fluid refractory patients.[13]

Cardiovascular agents used to support circulation can be classified as inotropes, vasopressors, vasodilators, and inodilators. Inotropes improve cardiac contractility and can increase heart rate. Vasopressors increase systemic and pulmonary vascular resistance. Vasodilators reduce systemic and pulmonary vascular resistance and,

although not directly affecting myocardial contractility, improve cardiac output by decreasing afterload. Inodilators simultaneously improve cardiac contractility and reduce afterload. Purely by tradition, a commonly selected initial agent for vasoactive support is dopamine, which provides both inotropic support at lower doses (5–10 μg/kg/min) and increased vasomotor tone at higher doses (>10 μg/kg/min). Often it is necessary to escalate the dopamine dosage to high levels (≤20 μg/kg/min), at which point additional agents should be strongly considered. More recently, the use of dopamine as an initial agent has been de-emphasized in favor of norepinephrine and epinephrine. The decision of which second agent to start should be based on the following determinations: whether the cardiovascular compromise is related to inadequate cardiac output from direct cardiodepressant effects, which requires increased inotropy; decreased vascular tone, which requires vasopressors; or increased afterload from vasoconstriction, which requires peripheral vasodilators. Afterload reduction in the context of septic shock is unlikely to be of benefit in a patient who is not adequately fluid resuscitated. There is not a single strategy meeting the needs of all patients. Consequently, the therapeutic options must be individualized and adjusted according to the patient's response.[14,217] In this regard, the clinician can often be assisted by garnering additional data on the basis of invasive monitoring.

Invasive Monitoring

The final step in the initial resuscitation of a child with sepsis is placement of appropriate and necessary vascular access and monitors. However, attention to the clinical examination as part of the ongoing assessment is imperative. In sepsis, the primary clinical end points to assess are changes in level of consciousness, decreased urine output, and poor peripheral perfusion characterized by delayed capillary refill and diminished distal pulses. Unfortunately, children with sepsis can be difficult to examine because they are often tracheally intubated and sedated and may not have produced any initial urine because of severe hypovolemia. Also, they frequently are receiving vasopressors (sometimes excessively), which can make examination of the skin for assessment of perfusion less reliable. For these reasons, invasive monitoring is often necessary and helpful.

Central venous access is a necessity for the child in septic shock. The decision to place a central venous catheter in the internal jugular, subclavian, or femoral position is dictated by a number of factors, such as the experience level of the operator, presence of coagulopathy, and possibility of monitoring central venous pressure and central venous oxygen saturation. Central venous catheters provide access for reliable delivery of vasoactive medicines and large volumes of fluid. However, they can also be used to obtain a measurement of central venous pressure (CVP) and, depending on location, may provide an approximate measurement of the mixed venous oxygen saturation.[217-219] Femoral catheters, in the absence of abdominal pathology, can be used to estimate CVP with good correlation.[219] Although use of CVP is common in clinical practice, the measurement of CVP in isolation cannot reliably estimate volume status or preload of the heart, as it depends on the interactions of cardiac function, cardiac compliance, and intravascular volume.[220,221] For example, a low CVP may be present with hypovolemia and normal cardiac function but may also be present in a patient with normovolemia and a

hyperdynamic status. On the other hand, a high CVP can be observed in hypervolemic patients but also in normovolemic, or even hypovolemic, patients with cardiac dysfunction. Factors that can elevate CVP even in the presence of hypovolemia include pulmonary hypertension, right ventricular dysfunction, tricuspid regurgitation, high positive end-expiratory pressure, high abdominal pressure, cardiac tamponade, and intracardiac left-to-right shunts. Thus CVP measurements need to be interpreted in the context of the specific clinical situation and patient.

The measurement of CVP without corresponding direct or indirect measurement of cardiac output also may not discriminate fluid responsiveness.[220] The hemodynamic response to fluid load can be estimated with the application of a fluid challenge, which is the rapid infusion of a fluid bolus of sufficient magnitude to increase CVP by approximately 2 mm Hg. A change of CVP of this magnitude will typically produce, in fluid-responsive patients, a significant change in cardiac output. When a direct measure of cardiac output is not available, other surrogates, such as central venous oxygen saturation, can be followed. A practical maneuver simulating a fluid challenge procedure is passive leg-raising. Passive leg-raising to 45 degrees increases venous return and transiently increases cardiac output and blood pressure in a fluid-responsive patient.[222,223] It is important to emphasize, however, that the identification of a fluid-responsive patient does not necessarily mean the patient needs additional large volumes of fluid.[222]

Accurate determination of the true mixed venous saturation in the pulmonary artery requires a pulmonary arterial catheter (PAC), but approximations of the saturation can be provided by a catheter tip at or near the right atrium. Values of oxygen saturation measured at the right atrium or superior vena cava are slightly different from true mixed venous saturation, but there is a good trend correlation between the two measurements.[217,224,225] Therefore the use of central venous (right atrium or superior vena cava) oxygen saturation is more practical and feasible as it avoids the requirement for pulmonary artery catheterization. Because of significant differences in oxygen extraction among the upper extremities, abdomen, and lower extremities, venous saturations from a femoral venous line do not accurately correlate with those measured in the pulmonary artery.[219] Measurements of central venous saturation can be achieved through the analysis of blood samples collected from correctly positioned catheters (intermittent) or continuously with the utilization of an indwelling fiberoptic catheter.

In the face of severe sepsis and septic shock, an intraarterial catheter may become necessary. An arterial catheter becomes both a source of continuous clinical information regarding blood pressure, pulse pressure, hemodynamic variation with respiration (ie, pulses paradoxus), and an access for frequent blood draws. Whereas blood pressure alone does not always equate to tissue perfusion because of differences in regional perfusion and vasoconstriction, a fluid-resuscitated child with normal or high systolic blood pressure will be more tolerant of manipulations to increase perfusion (ie, afterload reduction) than children with lower blood pressures. This condition occurs in children who have poor ventricular ejection and high systemic vascular resistance. Therapeutic maneuvers to actively decrease afterload can be more rationally conducted with continuous blood pressure monitoring via an intra-arterial catheter.

The arterial blood also provides the most accurate information regarding arterial

oxygen content that can be used to both assess the function of the lungs and maximize oxygen delivery. Additionally, analysis of the arterial pulse wave can provide a continuous monitoring of the cardiac output. Recent studies reveal this cardiac output estimation technique can be safely applied in children and has a reasonable correlation with thermodilution or echocardiography-based techniques.[226,227]

Use of PACs to optimize left ventricular preload, monitor changes in cardiac index, and provide accurate measurements of oxygen delivery and consumption is now controversial. Interpretation of PAC data requires the absence of intracardiac shunting and presence of normal mitral valve function as either shunting or mitral regurgitation alters cardiac index determination and pulmonary capillary wedge pressure measurements. Because data from critically ill adults showed no benefit of routine PAC use,[228] the use of PACs has substantially declined in critical care medicine but is thought to be of potential benefit in selected patients.[229] In light of studies showing the information obtained from PAC can be important in identifying clinically meaningful cardiovascular conditions different from what is suspected by clinical impression,[13,229] PAC placement may be considered for pediatric patients who remain in shock after resuscitation and initiation of the usual cardiovascular agents and in patients having unclear fluid status and cardiac function. Other methods of measuring cardiac output, such as arterial pulse wave analysis, femoral artery thermodilution, Doppler ultrasound, or ultrasound cardiac output monitoring, may be effective substitutes to the use of PAC.

Elimination of Pathogens

Identification of the source of a possible offending organism in septic shock dictates the choice of antimicrobial coverage and is important to long-term outcome, as early administration of appropriate antibiotics is associated with improved survival.[230-232] While the imperative nature of prompt antibiotic treatment may seem intuitively obvious, it has been well documented that delays in appropriate antibiotic administration have a greater adverse impact on septic shock outcome than do cytokine polymorphisms.[233] Therefore antibiotic therapy should be started within the first hour of recognition of sepsis, ideally after appropriate cultures have been readily obtained. However, antibiotic administration should not be delayed if obtaining appropriate cultures is technically problematic.

The offending organism and the site of infection also affect prognosis.[234] Fungal infections are associated with the lowest survival rates, followed by bacterial infections, especially meningococcal and pneumococcal infections.[2] It is important to note, however, the epidemiology of pediatric sepsis is changing, particularly in populations where vaccination policies incorporate immunization against *Haemophilus influenzae, Streptococcus pneumoniae,* and *Neisseria meningitidis* serotype C. Although infections caused by these agents have decreased, there are now more cases of nosocomial infections, especially caused by staphylococci and fungi. The majority of infections causing severe sepsis are respiratory or primary bacteremia, with respiratory cases being more common among older children and in community-acquired infections, and primary bacteremia more frequently affecting neonates, children with neoplastic disorders, or other comorbidities. Lower survival rates are associated with endocarditis and infections of the central nervous system.[2]

Initial empiric antimicrobial therapy should include one or more drugs having activity against the likely pathogens (bacterial or fungal) and the ability to penetrate into the presumed source of the sepsis. The choice of drugs should be guided by the susceptibility patterns of microorganisms in the community and in the hospital.[230] Because of the importance of appropriate antimicrobial therapy, the decision regarding which agents to start empirically must balance potential side effects against maximizing coverage. Initially, broad antibiotic coverage should be started. Neonates should be given ampicillin and either gentamicin or a third-generation cephalosporin such as cefotaxime. In infants and children older than 4 to 6 weeks, the decision to begin vancomycin therapy empirically, in addition to the standard third-generation cephalosporin, should be considered in light of the increasing antibiotic resistance of *Streptococcus pneumoniae,* as well as methicillin-resistant *Staphylococcus aureus.* Nosocomial infections and infections in immunocompromised patients require additional coverage for the possibility of *Pseudomonas* species and other resistant organisms. Acyclovir should be given if there is a clinical presentation or suspicion of an overwhelming viral (herpetic) infection, particularly in neonates and infants. Starting antifungal medicines initially in an immunocompetent child is usually not necessary. However, this decision should be reconsidered if the child does not improve over the first 2 days or in case of higher risk for fungal infection (presence of indwelling devices, immunosuppression, or other significant comorbidities). The antimicrobial regimen should be reassessed after 48 to 72 hours on the basis of microbiological and clinical data with the goal of narrowing the antibiotic spectrum to prevent the development of resistance and to reduce toxicity. Once a causative pathogen is identified, there is no evidence that combination therapy is more effective than monotherapy for most bacterial infections. The duration of therapy should typically be 7 to 10 days and guided by clinical response.[230]

Maintenance of Oxygen Delivery

After initial resuscitation and attention to pathogen elimination, ongoing management of sepsis remains primarily supportive, with particular attention to maintenance of adequate oxygen delivery. While this is a fundamental tenet of critical care medicine, the approach may be relatively ineffective in a subset of patients having impaired utilization of oxygen despite adequate oxygen delivery (ie, cytopathic hypoxia). The assessment of adequate oxygen delivery should be viewed as a dynamic and ongoing process as measured by a combination of parameters including clinical assessment of perfusion, blood pressure, serial lactate measurements, urine output, central/mixed venous oxygen saturation, and, in selected cases, PAC-derived measurements.[210]

Adequate preload is necessary for adequate cardiac output and consequently for adequate oxygen delivery. Children with sepsis can remain at risk for hypovolemia after an appropriate initial resuscitation because of persistent increased insensible fluid loss, increased vascular capacitance, and capillary leak with third spacing. Anecdotally, some well-resuscitated children have such vigorous urine output after the initial resuscitation that reassessment of fluid balance after the first 24 hours of presentation to the ICU reveals the fluid balance may actually be close to “even.” Thus providing adequate preload to the patient in septic shock may require

increased fluid administration for several days after the initial resuscitation. The choice of fluid to be used in this process is controversial, although there is general agreement the fluid choice should be isotonic. The three broad choices of fluids are crystalloid, non–blood colloid, and blood products. As evident when calculating the arterial content of oxygen, maintaining an adequate hemoglobin level is an important factor in providing adequate oxygen delivery. Although there is no clear recommended hemoglobin level for children with sepsis, one recent study showed that in patients with central venous oxygen saturation <70%, transfusion of packed red blood cells in combination with other measures to increase oxygen delivery is associated with improved outcomes.[210]

After initial resuscitation, ongoing myocardial dysfunction and altered vascular tone are likely to persist and will therefore require ongoing titration of cardiovascular drugs to maintain adequate oxygen delivery. Many patients will require titration of inotropes and vasopressors simultaneously, and it must be emphasized this will likely be a dynamic process requiring constant reassessment of the aforementioned indicators of adequate oxygen delivery. It is important to recognize that blood pressure alone as a goal may not correlate with optimal tissue perfusion and oxygen delivery. This concept is best illustrated by the subset of patients with septic shock who benefit from afterload reduction (ie, vasodilation). Patients with high SVR and low cardiac output, who have adequate preload, can benefit tremendously from inodilators such as milrinone.[235,236] Alternatively, this subset of patients can also benefit from pure vasodilators such as the NO donor, nitroprusside (in combination with a pure inotrope). After institution of afterload reduction, these types of patients may actually have lower blood pressures than one would typically target but will have enhanced tissue perfusion and oxygen delivery.

A subset of patients will have refractory shock despite optimization of the previously mentioned management strategies. In this subset, the institution of extracorporeal membrane oxygenation (ECMO) is recommended as a consideration in the context of refractory shock.[189] Anecdotal and subjective experiences suggest institution of ECMO support for refractory septic shock can be lifesaving in a subset of patients. The challenges that come with institution of ECMO include the definition of refractory septic shock, timing of ECMO initiation before the onset of irreversible end-organ failure, and ensuring ECMO support is not prematurely or unnecessarily instituted in patients who can be effectively managed with conventional support (ie, not exposing patients to unnecessary risks).

A summary of approaches to improving the relationship between oxygen delivery and oxygen consumption is provided in Box 111.3.

Box 111.3

Means of Altering the Relationship Between Oxygen Delivery and Oxygen Consumption

Means of improving oxygen delivery:

- Increase cardiac output

- Increase stroke volume

- Increase preload (volume resuscitation)
- Increase contractility (administration of inotropes)
- Decrease afterload (administration of vasodilators)
- Increase heart rate (rarely a therapeutic goal in sepsis management)
- Increase arterial oxygen content
- Increase arterial oxygen tension (administer oxygen, apply positive pressure ventilation, etc.)
- Increase arterial oxygen-carrying capacity (transfusion of packed red blood cells)
- In select cases, cardiac output and arterial oxygen content can both be increased through the institution of venoarterial extracorporeal membrane oxygenation

Means of decreasing oxygen consumption:

- Avoid/manage hyperthermia
- Remove work of breathing
- Administer sedation
- Administer paralytics

Additional Management Considerations

Patients with sepsis may have poor nutrition before presentation and often are not fed during the first few days of illness. Because of an increased metabolic rate and poor nutrition, patients with sepsis are frequently catabolic and at risk for development of protein calorie malnutrition.[237] Intestinal ischemia in association with loss of the mucosal barrier from malnutrition is associated with translocation of bacteria and endotoxin from the intestine into the bloodstream. Use of enteral feeding in critically ill patients has been shown to improve survival and decrease hospital stay.[238] The benefit of enteral feeding should be balanced with the risk of stressing intestinal function in the face of poor splanchnic perfusion, especially in the presence of vasopressors such as epinephrine and norepinephrine.[239] Regardless of the feeding mode, adequate nutrition and nitrogen balance are important for maintaining adequate host immune function and achieving homeostasis, as malnutrition adversely affects immune function. Finally, in the absence of enteral feedings, pharmacologic prophylaxis against stress-related gastrointestinal bleeding

is recommended by the most recent guidelines.

A positive fluid balance, as a consequence of aggressive fluid resuscitation and capillary leak, is an important issue that eventually needs to be addressed in virtually all patients with septic shock. The absolute level of positive fluid balance requiring active management seems to be highly variable and context specific in children with septic shock.[209] General signs of clinically significant positive fluid balance include hepatomegaly, rales/pulmonary edema, ascites and potentially intra-abdominal hypertension, and/or 10% increase in body weight. For many patients, institution of diuretic therapy is a simple and effective approach to manage a positive fluid balance, in the context of hemodynamic stability and adequate renal function. However, acute kidney injury/renal failure commonly occurs in septic shock and may require institution of some form of renal replacement therapy such as peritoneal dialysis, hemodialysis, or continuous renal replacement therapy (CRRT).

Variations of CRRT are commonly viewed as the most ideal choice for these patients given the potential ability to meticulously titrate fluid removal in patients with hemodynamic instability. In addition, CRRT has the potential to achieve more than simple fluid removal inasmuch as high ultrafiltration rates can also provide clearance of standard waste products of metabolism, as well as "mediators" of sepsis (ie, immune modulation). However, CRRT is also well documented to be associated with clinically significant complications (eg, hemodynamic instability and electrolyte imbalances) in critically ill children.[240] Thus "timing" and "dose" are important considerations for institution of CRRT in patients with septic shock, and both considerations are predicated on the concept that CRRT represents more than just simply fluid removal and management of uremia.[241] "Timing" refers to the concept of instituting CRRT before the onset of overt renal failure and clinically significant fluid overload. "Dose" refers to the concept of ultrafiltration rates and the potential ability of high filtration rates to achieve more effective immune modulation. These important concepts represent major challenges in the field that need to be addressed by well-designed, pediatric-specific multicenter trials. Recent trials comparing high ultrafiltration rates (high-intensity CRRT) with standard ultrafiltration rates (low-intensity CRRT) have shown no survival benefit in critically ill adults.[242,243] Intriguingly, there was trend toward improved survival in the subset of patients with sepsis treated with high-intensity CRRT[242] (see also Chapter 78).

Hyperglycemia is well recognized to be associated with increased morbidity and mortality in critically ill patients, including children with sepsis.[244,245] In 2001, van den Berghe et al.[246] published a landmark study demonstrating that aggressive insulin therapy to normalize glucose levels to within a narrow range significantly increased survival in a large cohort of critically ill adult surgical patients. This study strongly suggested that hyperglycemia is not merely a stress-related epiphenomenon of critical illness but rather a pathologic process that can be addressed by an intensive insulin-based protocol targeting normalization of glucose levels. However, the inability to consistently replicate these findings has led to a great deal of controversy in the field. A recent meta-analysis concluded that tight glucose control does not significantly reduce mortality in critically ill adult patients but is associated with an increased risk of hypoglycemia.[247] An even more recent, randomized, multicenter trial compared intensive glucose control (81−108 mg/dL) with conventional glucose control (<180 mg/dL) in more than 6000 critically ill adults.[248] This study concluded that intensive glucose control increased mortality in critically

ill adults, relative to conventional glucose control. Finally, another recent trial focused on intensive insulin therapy in adults with sepsis demonstrated no survival benefit but an increased risk of clinically significant hypoglycemia.[249]

The most current pediatric-specific sepsis guidelines recommend insulin therapy to maintain glucose levels ≤150 mg/dL and avoiding hypoglycemia by keeping glucose levels ≥80 mg/dL.[189] This is a level-3 recommendation (adequate scientific evidence is lacking but widely supported by available data and expert opinion) but was generated before the publication of two recent trials investigating intensive insulin therapy, specifically in critically ill children.[250,251] In the first trial published by Vlasseaers et al.[250] in 2009, the majority of patients (~75%) were surgical patients undergoing correction of congenital heart malformations. Intensive insulin treatment resulted in improved short-term outcomes (decreased ICU length of stay and decreased parameters of inflammation) but also resulted in a 25% rate of hypoglycemia. Macrae et al.[251] subsequently completed a landmark randomized trial of hyperglycemic control in critically ill pediatric patients and demonstrated no significant effect on major clinical outcomes, defined as mortality and absence of ventilation at 30 days. The incidence of hypoglycemia was again noted to be higher in the tight glycemic control group. However, there are no large pediatric-specific trials addressing insulin-based glucose control specifically in the context of septic shock. Therefore in light of the current data, and taking into consideration the risks of hypoglycemia in children, a reasonable glucose level to target seems to be ≤180 mg/dL pending a formal study. We await the results of the Heart and Lung Failure–Pediatric Insulin Titration Trial (NCT01565941) to further inform this important issue (see also Chapter 85).

Immune Modulation

Because immune/inflammatory dysregulation is a well-accepted pathophysiologic concept in septic shock, there has been a great deal of effort in developing treatment strategies directly targeted at immune/inflammatory modulation. Steroids have long been proposed as a general antiinflammatory strategy. In many clinical settings, patients with septic shock demonstrate worsening of their shock temporally associated with antibiotic administration. It is thought this phenomenon results from a massive release of bacterial toxins after antibiotic-mediated bacterial killing and a subsequent inappropriately exuberant immune/inflammatory response. However, the use of high-dose steroids to blunt this response is now universally accepted to be of no benefit and potentially harmful.[252,253]

A more recent approach to using steroids in septic shock involves the concept of relative adrenal insufficiency and an association between relative adrenal insufficiency and catecholamine refractory shock.[254,255] A landmark study by Annane et al.[256] demonstrated a substantial benefit in adults with septic shock having "relative adrenal insufficiency" (based on cortisol levels and ACTH stimulation testing) and treated with replacement hydrocortisone. However, a subsequent trial did not demonstrate the efficacy of hydrocortisone replacement, thus leading to an ongoing, unresolved controversy in the field.[257,258] Further, Boonen et al.[259] recently reported a reduction in cortisol metabolism related to suppressed expression and activity of cortisol-metabolizing enzymes during adult critical illness, thereby adding another confounding variable when considering administration of

corticosteroids for septic shock.

Conflicting data and controversy also exist in the pediatric septic shock population, and existing data are currently limited to meta-analyses, observational studies, and practitioner anecdotes and experience.[260-263] Recently, a retrospective analysis of an existing transcriptomic database of pediatric septic shock demonstrated that the administration of corticosteroids in pediatric septic shock was associated with repression of genes corresponding to adaptive immunity, raising questions about potential harm associated with corticosteroid administration during septic shock.[164] Jardine et al.[164] examined genes involved in cortisol synthesis, metabolism, and activity in critically ill pediatric patients using tag single nucleotide polymorphism (SNP) methodology. They identified an SNP in the *MC2R* gene (which codes for the ACTH receptor) and demonstrated that the AA genotype was associated with a low free cortisol response to critical illness. A recent report described the development and validation of a real-time subclassification method for septic shock using previously identified gene expression–based subclasses, which corresponded to genes for adaptive immunity and glucocorticoid receptor signaling.[185] The study reported that allocation to the subclass with decreased expression of the glucocorticoid receptor signaling pathway genes was independently associated with increased mortality, and adjunctive corticosteroid administration to patients in that subclass was independently associated with almost four times the risk of mortality.

It is possible that patients with septic shock and high levels of illness severity stand to benefit the most from adjunctive corticosteroids. Funk et al.[264] recently stratified a large cohort of adults with septic shock into quartiles of illness severity using APACHE II scores. Corticosteroid administration was associated with decreased mortality for patients in the highest quartile of illness severity.[264] In contrast, when a large cohort of children with septic shock was stratified for baseline mortality risk using stratification biomarkers, corticosteroids were not associated with decreased mortality for patients in the intermediate or high baseline mortality risk groups.[265]

The role of hydrocortisone replacement in pediatric septic shock represents another major challenge in the field that must be directly addressed by a large, multicenter, randomized trial. Current barriers to conducting this important trial include lack of equipoise in the pediatric critical care community, lack of consensus regarding the definition of relative adrenal insufficiency, and our inability to select which patients with septic shock are most likely to benefit from adjunctive corticosteroids.[188,266] Thus at present treatment guidelines suggest hydrocortisone replacement therapy be considered for patients who appear refractory to resuscitative measures, have a known history of adrenal insufficiency, have already received exogenous steroids, or have an abnormal ACTH stimulation test result.[189] Given the lack of objective evidence supporting the efficacy of adjunctive corticosteroids, as well as accumulating evidence suggesting harm, the otherwise strong recommendation for corticosteroids in the current pediatric guidelines should be revised accordingly.

Because the pathophysiology of septic shock is directly linked to circulating pathogen-derived toxins and circulating inflammatory mediators, removal of these molecules via hemofiltration or exchange transfusion (ie, plasmapheresis) has been hypothesized to improve outcome. Both hemofiltration and plasmapheresis were

discussed in previous sections. The fact remains that these approaches, while theoretically well founded, remain to be proven and cannot be recommended routinely in the absence of more objective data. Both strategies carry significant risks that must be weighed against the potential theoretical benefits. These include difficult vascular access in smaller children, fluid and electrolyte imbalance, hypothermia, anticoagulation requirements because of extracorporeal circuits, and acutely altered hemodynamics when instituting therapy. In addition, beneficial proteins such as albumin, immunoglobulins, clotting factors, and counterregulatory cytokines may be removed to the detriment of the patient.

Part of the inflammatory response involves cytokines causing widespread activation of the coagulation cascade with suppression of fibrinolysis, as described in previous sections. Disseminated intravascular coagulation has been implicated in the etiology of multiple organ injury leading to MODS and is directly linked to alterations of endogenous anticoagulants such as antithrombin III and protein C. While recombinant forms of these anticoagulants are available, they have not been demonstrated to be efficacious in the pediatric population and carry significant risks of serious adverse events due to bleeding.

As previously described, multiple antiinflammatory strategies have been attempted and some are now being reconsidered. These include anti-TNF, anti-IL1, antiendotoxin, TLR-4 antagonists, and anti-PAF strategies. Thus far none of these strategies have proven to be of sufficient clinical benefit in septic shock to warrant formal approval as standard of care. It is hoped that better-designed studies that carefully stratify patients, consider the presence or absence of an offending pathogen, and possibly identify genetic factors influencing outcome will provide insight into the appropriate immunomodulating agents clinically beneficial to pediatric patients with septic shock.[267]

An alternative approach to immune modulation in septic shock focuses on immune “enhancement” rather than inhibition of inflammation. As emphasized in previous sections, the paradigm of sepsis as an adaptive immune problem is increasingly gaining credence in the field. Thus there is now growing attention to the use of potentially immune-enhancing agents such as interferon-γ, granulocyte-macrophage colony-stimulating factor, zinc, selenium, prolactin, agonist antibody to CD40, PD-1 inhibitors, and IL-7.[19,187,268-271] Thus the next major advance in the clinical septic shock management may involve one or more of these immune-enhancing approaches rather than an antiinflammatory approach.

Case for More Effective Stratification in Pediatric Septic Shock

The vast majority of interventional clinical trials in septic shock have failed to demonstrate efficacy of the particular test agent. A potential reason for failure in these trials is not because the biological/physiologic principle being tested was fundamentally flawed. Rather, the primary reason for failure lies in the inability to effectively address the substantial heterogeneity characterizing the syndrome of septic shock. As indicated throughout this chapter, septic shock is a heterogeneous syndrome with the potential to negatively and directly affect all organ systems, and this heterogeneity has consistently challenged multiple investigators attempting to

evaluate the efficacy of various experimental interventions. As astutely stated by Marshall, a key challenge in the field is to reduce and manage this heterogeneity by more effectively stratifying patients for the purposes of more rational and effective clinical research and clinical management.[272] The concept of preintervention stratification in sepsis and its positive impact on the efficacy of an experimental therapy was corroborated by the Remick laboratory in a murine model of polymicrobial sepsis.[34]

One potential strategy for stratifying children with septic shock involves early identification of septic shock endotypes based on genome-wide expression patterns. As described earlier, endotypes of pediatric septic shock have been identified exclusively on the basis of on gene expression profiling conducted within 24 hours of admission, and these expression-based subclasses have highly relevant differences in illness severity and mortality.[167-169,185] A similar strategy was demonstrated in adult patients suffering from trauma,[273] and recently Knox et al.[274] reported endotypes of adult sepsis on the basis of organ failure patterns. As high-throughput technologies evolve and validation studies are rigorously performed, the ability to conduct expression-based endotyping of pediatric septic shock could well become a clinical reality.[267]

Another potential strategy for stratifying children with septic shock is biomarker-based stratification. Many biomarkers can be readily measured in the blood compartment, thus providing a clinically feasible strategy for early stratification of patients. For example, IL-8 can be readily and rapidly measured in small-volume blood samples. IL-8 was found to be a robust outcome biomarker in children with septic shock.[38] Specifically, an IL-8 level, measured within 24 hours of admission to the pediatric ICU, was found to have a 95% negative predictive value for mortality in a derivation cohort of patients. The reliability of this assertion is supported by prospective, formal validation in an independent validation cohort of patients (the RESOLVE database), which demonstrated an identically robust negative predictive value.[38] A similar observation (98% negative predictive value for mortality) was found by measuring chemokine (C-C motif) ligand 4 (CCL4) serum protein levels within 24 hours of admission to the pediatric ICU with septic shock.[275]

It has been proposed that these types of sepsis outcome biomarkers (ie, biomarkers having high negative predictive values for mortality) could be used to stratify patients eligible for interventional septic shock trials.[38,275] Patients having a high likelihood of survival with standard care, but otherwise meeting entry criteria for a given interventional trial, could be potentially excluded from the trial on the basis of these biomarkers. Such a stratification strategy would serve to derive a study population with a more optimal risk-to-benefit ratio, thus improving the ability to demonstrate efficacy for a given test agent. This type of strategy would be particularly useful for a test agent carrying more than minimal risk.

Although single biomarker-based patient stratification is clinically appealing, it may not be sufficiently robust to meet all clinical and research needs from the combined standpoints of specificity, sensitivity, and positive predictive values. Indeed, the aforementioned studies involving IL-8 and CCL4 had clinically unacceptable specificities, sensitivities, and positive predictive values, relative to the very high negative predictive values. The ideal biomarker-based stratification tool, which would meet a wide range of clinical and research needs, would simultaneously have high specificity, high sensitivity, high positive predictive value,

and high negative predictive value.

Given the biological complexity of pediatric septic shock, a stratification strategy based on a panel of multiple biomarkers has more potential to meet the needs of the aforementioned ideal biomarker-based stratification tool. To this end, the Pediatric Sepsis Biomarker Risk Model (PERSEVERE) was derived and validated.[178,179,182] PERSEVERE incorporates a panel of biomarkers into a decision tree derived using Classification and Regression Tree (CART) methodology. The terminal nodes of the decision tree provide a range of reliable baseline mortality probabilities for children with septic shock. Fig. 111.5 depicts the PERSEVERE decision tree.

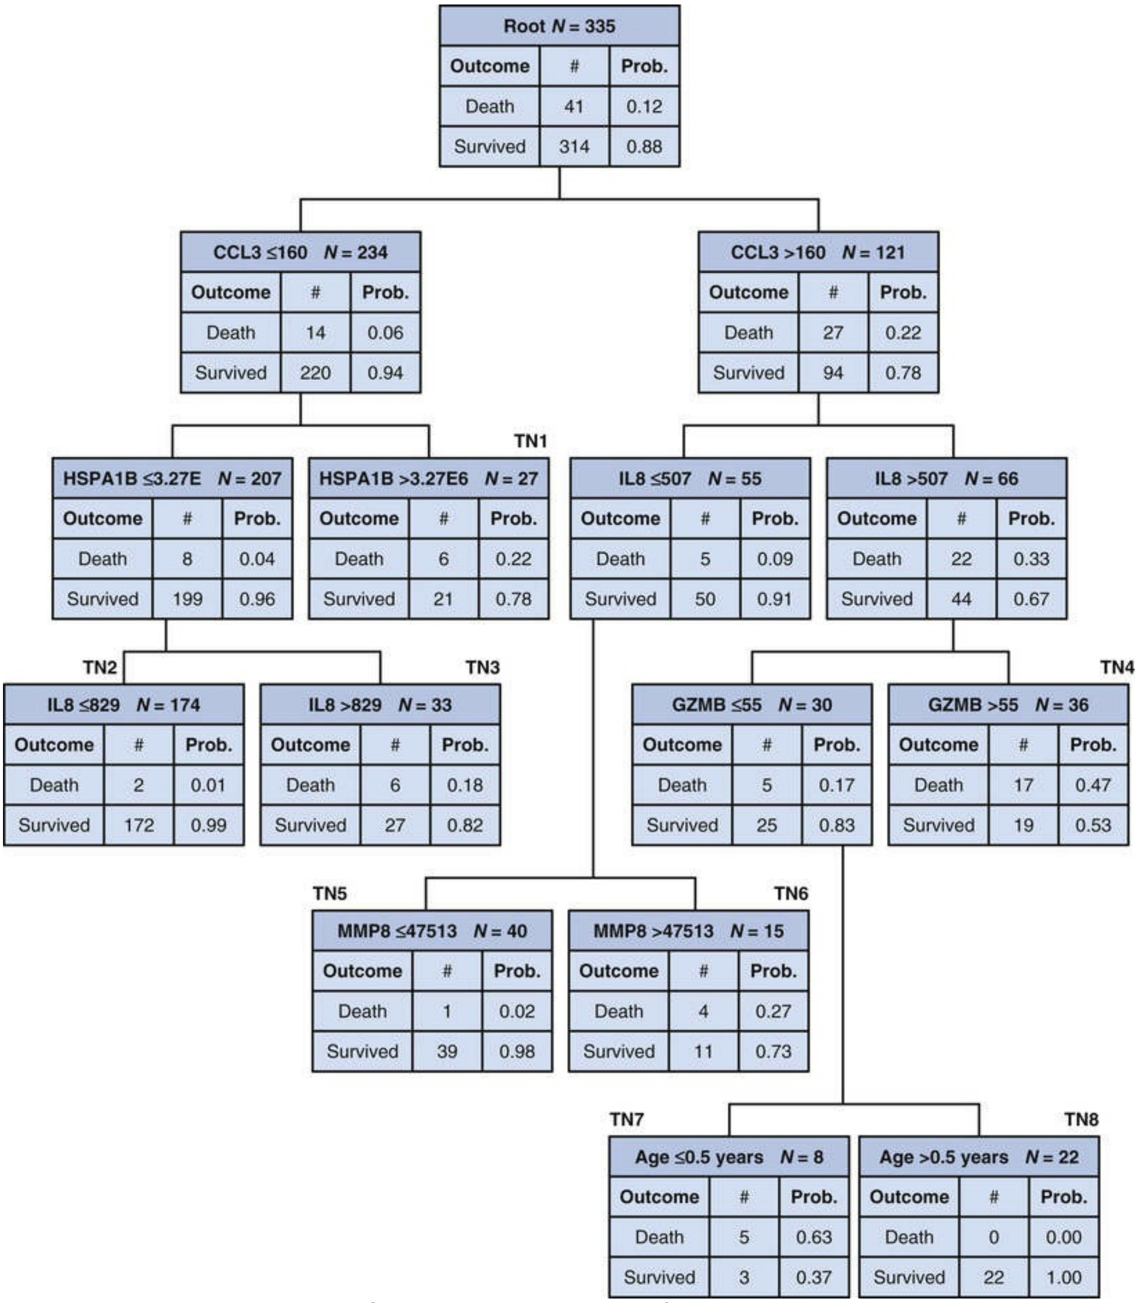

FIG. 111.5 The PERSEVERE decision tree for assigning a baseline mortality probability for children with septic shock. The decision tree is based on six biomarker-based decision rules and one age-based decision rule. The stratification biomarkers used for analysis are as follows: C-C
